Two families of fused abrasive minerals require specific cooling equipment able to cool the liquid composition down as fast as possible; these are the alumina/zirconia products and polycrystalline corundum.

The fused alumina composition with 42% (eutectic composition) or 25% zirconia requires that the liquid phase is quenched to get the typical fine dendritic microstructure for such a product (see Fig. 6). The second important characteristic of such products is the ratio between the ZrO₂ high temperature phases cubic + tetragonal to the sum of the three ZrO₂ phases cubic + tetragonal + monoclinic. This ratio called the T factor (measured by X-R-ay diffractometer and the Rietveld method) is linked to the performance of this abrasive mineral. The maintenance of good self sharpening effects during grinding operations giving higher stock removal and longer life time is greater compared to standard fused abrasive minerals. For the eutectic composition the T factor must be above 90%. For the composition with 25% Zirconia the target is the opposite: the T factor being <30% to get a higher toughness and a lower friability index. Many patents claim the effect of additives like TiO₂, Y₂O₃, MgO, CaO can control this T factor (Marlin *et al.*, 2011; Fischer *et al.*, 2012; Gebhardt, 2015).

Only one producer is able to produce a polycrystalline fused corundum (Fig. 4) using a proprietary fast cooling process (Alary and Sachse, 2012). Such grit performs like ceramic grains obtained by sintering processes despite their coarse elementary crystal size, are fine for an electrofused product but still too coarse for a sintered product (Fig. 7).

An other specific product in this family of fused alumina mineral is the so called “blue fired brown corundum” which is a regular or semifriable abrasive. A perfect example of surface modification in the field of abrasive. When you apply a heat treatment under controlled atmosphere and temperature in the range of 1100°C +/- 100°C the brown corundum changes color. To explain this phenomenon we have to come back to the origin of color in natural mineral like sapphire which is the natural blue

Fig. 7 Polycrystalline fused corundum mineral, a singular product in the electrofused minerals family, working like a sintered ceramic grain. Internal porosity: 15%–20%; CFF: 40N; Friability index:11. Courtesy Imerys Fused Minerals.

corundum having the same impurities, Fe and Ti, substituted in the atomic lattice. (Nassau, 1978, 1987; Moon and Phillips, 1994). During this heat treatment such impurities move to the surface of brown corundum grains which increase the probability of finding Fe^{2+} and Ti^{4+} in adjacent sites in order to realize the electronic exchange described by the oxidation-reduction equilibrium mentioned Fig. 8. The energy (around 2 eV) linked to this electronic transfer is related to the yellow/orange color absorption. Blue is the complementary color of the yellow one. The color change is one thing, but for the abrasive users the interest is that during this heat treatment mechanical and surface properties of the brown fused corundum change. Thus its friability index decreases and toughness and hardness increase leading to an increase in abrasive performance compared to the original brown fused grain.

To conclude this part related to electro fused process, some words about SiC production. Developed by E. Goodrich Acheson end of the nineteenth century the SiC production process is well described by the following web site: see “Relevant Websites section”. A blend of carbon and silica sand react in the electric arc of the two electrodes furnace following the reaction

From this high temperature reaction ($> 2000^\circ\text{C}$) two SiC qualities are produced. In the core area α -SiC the highest grade with coarse grains and in the peripheral area β -SiC is a metallurgical grade with a lower purity $92\% < \text{SiC} < 98\%$. The drawback of this very old process is a huge production of CO and some modifications have been proposed to overcome this problem (Aleonar *et al.*, 2013). The next steps of the production process are similar to those for the production of fused alumina abrasives (Fig. 5).

Depending on the targeted application, the shape of the abrasive grains and not just their size changes the performance of the abrasive tool drastically. For the same equivalent grit sizes an angular grit will have a lower pack density but sharp edges compared to a bulk grit. The first one will be better for cutting the second for grinding or polishing.

Like for fused alumina, all SiC producers for abrasive applications offer their products following the FEPA norm with at least two different loose pack density (LPD) that means different shape from angular to blocky (for SiC minerals see web site: see “Relevant Websites section”).

Fig. 9 Sintered abrasives production process following a standard technical ceramic process.

Sintered Abrasives

With fused polycrystalline alumina the limit of the arc furnace technology was reached to produce fine microstructures. To carry on the continuous improvement of manufactured products hard and more wear resistant, a new generation of synthetic abrasive minerals was developed. The sintered abrasives or ceramic grains are produced following processes and scientific approaches used in the field of technical and advanced ceramics.

Elementary crystal sizes of such ceramic grains are 10 to more than 100 times finer than the crystal size of fused polycrystalline abrasives. Their sale price is 10–20 times higher than price of electro fused abrasive but their performances warrant this higher price. With their very fine polycrystalline microstructure these ceramic grains generate new cutting-edges during machining operations. This self-sharpening effect enables enhanced lifetime and surface quality of machined components.

● Extrusion processes

The first generation of such ceramic grains used milled powders of alumina or calcined bauxite as raw materials to produce sintered alumina or bauxite with high density and fine microstructure, but still above a $1\mu m$ grain size. The main producers are Japanese: Showa Denko, Kure Norton and European: Saint Gobain, Alteo, Imerys Fused Minerals (Piquet and Madec, 2006; Tomikawa *et al.*, 2011, 2013). The flow sheet for the process is given in Fig. 9 with some additional photographs illustrating the product before and after sintering.

Table 3 Typical characteristics and rod size of sintered alumina & bauxite abrasive. The green coarser rods are crushed to produce the FEPA grit sizes up to F36 and finer. (courtesy Imerys Fused Minerals)

Main typical properties (%)	Sintered abrasives			
	Alumina	Bauxite	Rod sizes (mm)	
Al ₂ O ₃	99	80	#8	2.14–2.40
Fe ₂ O ₃	0.04	5–8	#10	1.87–2.13
Na ₂ O	0.15	0.1	#12	1.62–1.86

density (g/cm ³)	> 3.80	3.65–3.75	#24	0.67–0.89
Hardness <i>HK</i> (GPa)	18–19	16–17	#30	0.4–0.88
Friability index	<2	2		
CFF (N)	90 + / – 5	100 + / – 5		

Table 4 Typical chemical composition of calcined bauxite for abrasive application

Bauxite composition	%
Al ₂ O ₃	80–85
Fe ₂ O ₃	<10
SiO ₂	5 + / – 3
TiO ₂	<5
CaO	<1
K ₂ O + MgO	0.01–0.1

The rod shape is dedicated to a niche application: scarfing grinders for slabs of steel alloys. These rods are available in different diameters (see [Table 3](#)) with a ratio of length to diameter around 2. As shown [Fig. 9](#) these rods are obtained by extrusion of alumina or calcined bauxite ceramic paste through calibrated dies. Such “spaghettis” like extrusions either cut to give little rods or crushed to give regular FEPA grits after drying. They are finally sintered in rotary furnace. If it’s easy to find good technical grade of alumina for ceramic application (P172 SB Alteo, NO713 RF Nabaltec, CT3000SG Almatiss etc.). However, the production of abrasive sintered bauxite requires more attention. Before processing it is important to find the right crude bauxite with a high alumina content, calcine this crude bauxite to transform the alumina hydrate into reactive alumina and finally mill this calcined bauxite to a fine powder. [Table 4](#) gives a typical composition of such a calcined bauxite. After sintering a calcined bauxite abrasive is composed of 3 mains phases; α -alumina, Mullite (3Al₂O₃.2SiO₂) and Tialite (Al₂TiO₅). To perform as abrasive mineral, Mullite and Tialite phases must be limited. They weaken the mechanical properties of the material. To overcome the difficulty of finding good bauxite and to ensure reproducible properties, some producers developed synthetic bauxite by co-milling alumina powders with Ilmenite (Fe₂TiO₅) and Zircon (ZrSiO₄). With low amounts of silica and titanium oxides, such synthetic materials offer very low CFF values and friability index, hardnesses and toughnesses of the best sintered bauxite for this application ([Hirsch and Alary, 2015](#)). After sintering this co-milled composition gives a composite material has the main phases found in Bauxite doped with zirconia particles as re-enforcement.

● Sol-Gel process (the ceramic grains)

Although such high-tech ceramic grains do not represent not more than 15,000 to 20,000 tons per year production, they are at the origin of the most important patents and publications related to their very high performance in the most sophisticated of abrasive applications ([Nadolny, 2014](#); [Huang et al., 2021](#)).

Based on alumina and composites with an alumina matrix, the latest generations of ceramic grains were developed by Saint Gobain and 3M more than 30 years ago. With Sol-Gel ceramic grains we are in the World of Advanced Ceramic, materials having nano size crystal structure.

Applied to abrasive grain the sol-gel chemistry process can be generally described by [Fig. 10](#). Although the actual trend is to give a specific well designed shape geometry to enhance grinding quality and efficiency ([Erickson, 2011](#); [Keipert et al., 2011](#); [Welygan et al., 2012](#); [Monroe, 2013](#); [Yener et al., 2012](#); [Bauer et al., 2012](#)) the shaping step could only be a milling step of the dried gel before sintering.

The first key point being the crystal size reduction the addition of seeds to reduce the α -Al₂O₃ temperature is the rule. Numerous works in the scientific literature ([Kwon and Messing, 2000](#); [McArdle and Messing, 1993](#); [Li et al., 2011](#)) as well as patents (describe the addition of nano particles of α -Al₂O₃, Fe₂O₃, ZrO₂ to reach a sintered density closed to the theoretical one at temperatures more than 100°C below the usual sintering density for technical grade of alumina.

Fig. 10 Outline of the sol – gel process and photomicrograph of powder produced (bar = 1 μm).

Fig. 11 Alumina/magnetoplumbite sol-gel abrasive composite microstructure. Courtesy Imerys Fused Mineral.

A second key point was contributed by the 3M company which could be considered as the most innovative company in this field. Thanks to an additional step it was proposed to infiltrate the dried gel with lathana, yttria and magnesia salts to create, after sintering, a composite material named Cubitron 321™ (Wood, 2000), which has platelet crystals of magnetoplumbite as reinforcement of the alumina matrix. Such minerals are described by the general formula: $\text{PM}_{12}\text{O}_{19}$ with $\text{P} = \text{Pb}^{2+}$ and $\text{M} = \text{Fe}^{3+}$.

The magnetoplumbite compound found in the 3M product is described by the following chemical reaction and by the typical microstructure Fig. 11.

The fracture toughness of this composite reaches $\approx 4.5 \text{ MPa m}^{1/2}$ compared to $\approx 3 \text{ MPa m}^{1/2}$ for the pure alumina sol-gel abrasive. Hardness of such sol-gel alumina grains reaches between 22 and 24 GPa.

Fig. 12 Laser printing method to produce triangular grain shape. 3M™ patent WO 2012061033 A2.

The last improvement proposed by 3M company (Erickson, 2011; Keipert *et al.*, 2011; Welygan *et al.*, 2012) and followed by some others (Yener *et al.*, 2012; Bauer *et al.*, 2012) was to propose a calibrated shape using different shaping processes such as tape casting, molding, screen printing, laser printing (see Fig. 12).

With a well-designed grain shape, abrasive tools have longer life time, reduce the contact temperature and machining surfaces are cleaner. There are used for precision grinding wheels. Grinding mechanisms are well describe by Nadolny (2014) and Huang *et al.* (2021).

Application Guidance

Having designed the physical properties, grain shape, crystal size and microstructure of the mineral the abrasive producer is able to predict in which type of application the abrasive grain will offer the best performance, taking into account the economic point of view. Sol-gel abrasive grains cost 10 times the price of electro fused one. The qualities of the generic types of abrasives are summarized below.

- (1) BFA (brown fused alumina) – blocky and tough grain for all standard wheels on standard steel.
- (2) WFA (white fused alumina) – weak and friable grain for lab wheels or as blend for improving the cutting ability.
- (3) Semi-friable BFA – weak and tough grain, best price/performance ratio for smaller wheels.
- (4) Pink fused alumina – similar to WFA but longer lifetime.
- (5) Monocrystalline alumina – tough and sharp grain; best lifetime/cutting ability ratio.
- (6) AZ, fused alumina 25% zirconia – higher wear resistance of foundry wheels – mainly used for large diameter wheels in steel plants.
- (7) AZ, fused alumina 40% zirconia – higher wear resistance – due to the specific grain sharpness it matches good to stationary cut-off wheels and even thin wheels.
- (8) Silicon Carbide – hard and sharp grain, standard grain for stone cutting and good for aluminum, titanium.
- (9) Ceramic grain – microcrystalline structured grain with best performance on nearly all materials – self sharpening effect for a higher lifetime.

The final abrasive mineral performances are widely linked to firstly the ability of the abrasive tool manufacturer to make the best composite product. The bond between abrasive grain and his matrix resin or ceramic wheel is key. Thus, it is not in the manufacturers best interest to have a good abrasive grain if it's immediately ripped from the abrasive tool when machining. Secondly, the same product with excellent performance in one application may give the worst performance in the other one. Thus, there is little chance of success without a broad and deep knowledge of the coupling between mineral characteristics and the abrasive application.

Finally, it must be pointed out that there is no bad abrasive mineral, only abrasive minerals badly employed.

Wear and Erosion Resistant Ceramic Materials

Pavol Hvizdoš, Slovak Academy of Sciences, Košice, Slovakia

© 2021 Elsevier Inc. All rights reserved.

Introduction

Thanks to their crystallographic structure and strong interatomic bonds, modern ceramic materials have many excellent properties, such as high hardness, strength, high temperature and chemical stability, high resistance to corrosion and wear. Their weaknesses are low fracture toughness and low resistance to defects and cracks, and the resulting high brittleness and low reliability. To improve their performance in this respect, a lot of research work has been carried out in recent decades. Yet, despite the improvement of fracture toughness and strength of modern ceramic materials, they are still predominantly used in applications which make use of their exceptional hardness and chemical and thermal stability – such as cutting tools, ceramic seals, ball bearings, etc. – i.e., applications without high volume loads but with intense mechanical contact (Kato, 1990). Such applications require high wear resistance and good tribological behavior. Typical and industrially well proven materials include high purity alumina, tetragonal stabilized zirconia, alumina-zirconia-(silica) mixtures, nitride bonded silicon carbide (NBSiC), reaction bonded silicon carbide (RBSiC/SiSiC) (Medvedovski, 2001; Saint-Gobain, 2020 and others).

The resulting tribological performance depends on interplay of many factors. First, the material intrinsic properties, such as hardness, toughness, strength, ductility, and possible work hardening. Second, other (extrinsic) factors are equally important, such as forces applied, relative speed, environmental variables (temperature, atmosphere, humidity, lubrication). And third, the chemical nature of materials in contact, together with lubricants and environment, also play important role, as they determine the tribochemical reactions (Basu and Kalin, 2011).

Friction, especially in unlubricated situations, is a resistance to motion due to the interaction of solid surfaces in contact (Archard, 1953). Low friction is important for some applications, such as bearing, seals, hinges, biomedical joint implants. On the other hand, there are applications where high friction is desirable, like brake pads and tyres. In any case, it is important to have control over the specific friction for a particular application.

Wear is the progressive loss of material due to the tribological interactions at surfaces in contact and relative motion. Such solid body contact might be accompanied also by liquids and gases, thus wear includes various forms such as sliding, rolling, impact, cavitation, erosion. In general, wear is detrimental in many engineering applications, but also in those where it is desirable (grinding, polishing) it is important to have it under control and/or to be able to predict which conditions will have what sort of consequences.

Wear and Erosion Evaluation

In most cases the mechanical wear and erosion performance is observed in combination with a specific counterpart, in accordance with intended applications, or with chemically similar materials. In these types of tests, the sample surfaces are carefully prepared in a defined way, usually ground and polished to a specific surface roughness. According to the standard ISO 20808:2004E (2004) during the wear testing the normal loading forces are set or controlled. Tangential forces are continuously monitored, and from those the coefficient of friction is calculated and recorded. After finishing the test, the worn surfaces (wear tracks) are observed in microscopes, and based on these observations the wear regimes, types, and damage micromechanisms are determined. Typically, also the consequences on the surface (near surface layers) chemical composition are observed. If possible, the material loss due to wear is calculated. The specific wear rate (W) is evaluated as volume loss (V) per distance traveled (L) under an applied normal load (F_p): $W = V/(L F_p)$.

The erosive wear of brittle materials by hard particles bombarding a surface occurs by propagation and interaction of cracks produced by impacting particles. Like abrasion, it can involve both plastic deformation and brittle fracture, and the details depend on both the wearing material and the erodents, as well as on the condition of the impacts, like particle mass, velocity, and impingement angle. Gas blasting methods for evaluation of erosive wear are standardized in the ASTM G76 – 18 (2018) industrial standard.

Tribological behavior is, generally, a complex result of interaction of the material surfaces, which are in contact and in a relative motion. It is a complicated phenomenon which is impossible to exactly predict just from knowledge of other basic mechanical properties. That means, the wear testing for the development of new materials for tribological applications absolutely indispensable (Kato and Adachi, 2002). Wear of materials is usually characterized by its intensity (severity). Generally, it is divided to 'mild', 'severe' and 'ultra severe' regimes (Adachi and Kato, 1997; Kato and Adachi, 2002; Bhushan, 2001). In ceramics is this distinction is very well definable quantitatively. Ceramics are considered mildly worn, i.e., suitable for tribological parts, if their specific wear rate, W , is smaller than $10^{-6} \text{ mm}^3 \text{ m}^{-1} \text{ N}^{-1}$. The interval 10^{-6} – $10^{-5} \text{ mm}^3 \text{ m}^{-1} \text{ N}^{-1}$ is considered transitional, at $W > 10^{-5} \text{ mm}^3 \text{ m}^{-1} \text{ N}^{-1}$ it is 'severe wear', connected to more intense damage mechanisms and usually means insufficient performance for given application. At even higher wear rates ($> 10^{-2} \text{ mm}^3 \text{ m}^{-1} \text{ N}^{-1}$) 'ultra severe wear' is accompanied by thermal shock and massive surface damage (Table 1).

Table 1 General classification of the wear régimes in dry sliding

Wear regime	Wear rate [$\text{mm}^3 \text{m}^{-1} \text{N}^{-1}$]	Wear mechanisms
Mild wear (stress intensity $< K_{IC}$)	$< 10^{-6}$	(Asperity scale failure mode) Abrasion Intergranular cracks Subsurface damage/cracks Grain pullout Tribochemical
Severe wear (stress intensity $> K_{IC}$)	$10^{-5-10-2}$	(Nominal scale failure mode) Fracture mechanics Tensile cracks $\rightarrow$ edge effects 3rd-bodies (linked to grain pullout)
Ultra-severe wear (stress intensity $\gg K_{IC}$)	$> 10^{-2}$	(Nominal scale + few pieces large debris) Thermal shock (nominal scale)

Note: Modified according to Bhushan, B., 1999. Principles and Applications of Tribology. New York: Wiley and Sons.

Development of Ceramic Materials and Ceramic Matrix Composites for Improved Tribological Performance

In research of the ceramic materials for tribological applications, the material intrinsic properties are optimized in order to meet desired criteria for the specific use. First, control and selection of a suitable basic ceramic material is important. If needed, further tailoring of the material properties for industrial requirements can be achieved by designing specific composite materials – ceramic matrix composites. The benefit of using composites in this area is twofold: (1) possible improvement of fracture toughness and hardness can improve the wear resistance; (2) addition of appropriate secondary phases can lower the friction coefficient thanks to development of self-lubricating effects.

During the last two decades, an interesting development in ceramic matrix composites (based on alumina, zirconia, silicon nitride, silicon carbide, and others) with carbon nanoobjects (nanofibers – CNF, nanotubes – CNT, and graphene nanoplatelets – GNP) have led to promising results in the area of tribological properties (An *et al.*, 2003; Lim *et al.*, 2005; Balázsi *et al.*, 2006; Yamamoto *et al.*, 2008; Hvizdoš *et al.*, 2010b, 2011; Puchý *et al.*, 2013; Maros and Németh, 2017; Belmonte *et al.*, 2013 and others). It was shown that for self-mated tribological pairs the coefficient of friction could be significantly reduced. Fig. 1(a) summarizes the average values of the friction coefficients for alumina, zirconia, silicon nitride, silicon nitride matrix materials with CNT, CNF, or GNP. This reduction, however, was generally accompanied by a lowering of wear resistance (Fig. 1(b)), due to imperfections and defects in the microstructure caused by difficulties with proper distribution and incorporation of CNT/CNF/GNP. In some cases,

however, as seen in Fig. 1(b) for Si_3N_4 -CNT and Si_3N_4 -GNP there are advantageous effects, where abrasion resistance readily improved, most likely due to significantly reduced friction due to phenomenon of solid lubrication. These results will be further commented on for each class of materials.

Oxides I – Alumina Based Ceramics

Alumina (Al_2O_3) is a traditional fine ceramic material. It is one of the least costly and most often used structural ceramics. Its raw materials are cheap and easily obtainable. The most common modification, α - Al_2O_3 , is very strong and stiff. It has very high hardness and wear resistance, excellent dielectric properties from DC up to GHz frequencies, resistance against both strong acids and bases also at elevated temperatures, good thermal conductivity and excellent formability. It is readily available in high purities (99.5% for high temperature applications). Thanks to the excellent combination of properties and attractive price, fine grained high quality Al_2O_3 ceramics have a very wide range of applications. Typical ones are gas laser tubes, abrasion liners, sealing rings, high temperature and high voltage electrical insulators, furnace elements, fiber and wire guides, electronic substrates, ballistic armor, thermometric sensors, biomedical implants, laboratory tubes and sample holders, etc.

Since monolithic material is naturally highly wear resistant, the research effort has been aimed at lowering the coefficient of friction while possibly improving fracture toughness. One of the most interesting proposals was to use the newly developed and promising carbon structures - 1D (filaments, fibers, nanotubes) and/or 2D (graphite/graphene platelets) as composite fillers.

Alumina - CNT composites with a nanotube content of 0–12 wt% were prepared by different techniques by Lim *et al.* (2005) to investigate the influence of the production process on their tribological properties. The best tribological properties were obtained after application of tape casting, followed by lamination and hot pressing. Material loss of the composites was significantly reduced and the coefficient of friction was maintained with CNT additions of up to 12 wt%. CNT agglomeration, so often observed in conventional hot-pressed samples, was significantly suppressed and the CNT distribution was relatively homogeneous. Such efficient distribution of CNTs in the matrix contributed to better compaction of the composites and to better values for both mechanical and tribological properties.

In the work of Puchý *et al.* (2013) a decrease in the coefficient of friction for Al_2O_3 -5 wt% CNT, mainly due to the formation of a tribological film, was found. This behavior is quite stable at temperatures up to 500°C. For materials with the even higher CNT content ($\geq 10\%$), the advantageous low coefficient of friction is only manifested up to temperatures around 300°C, then it rises sharply.

An *et al.* (2003) found a 40% decrease in the coefficient of friction down to 0.3 for the 12 wt% CNT - Al_2O_3 composite. Yamamoto *et al.* (2008) for similar materials achieved a minimum friction with a coefficient of 0.3 for 4 wt% CNT content. According to these works, the rolling motion of the released CNTs, which remain in the area at the interface between the tribological partners, also contributes to the reduction of friction.

Interesting results have recently been obtained in the case of hierarchically grown graphene layers on alumina grains (Hussainova *et al.*, 2016), in which an optimum with a reduced friction coefficient and better abrasion resistance at very low carbon contents, below 1.5 wt% C, was found. Here, even though the amount of carbon filler is very low, its excellent distribution around some of the matrix grains guarantees its good effect. The coefficient of friction decreased from 0.65 to 0.5, while the wear rate decreased by 50%–60% in conditions of mild wear and by 90% in conditions of severe wear.

Oxides II – Zirconia Based Ceramics

Zirconium is found in nature in igneous rocks in the form of zirconia - ZrO_2 , but especially zirconium silicate - zircon (ZrSiO_4). Most of the zirconium materials, are used directly for the production of refractory materials. Zirconia occurs in three polymorphic modifications, monoclinic, tetragonal and cubic (Stevens, 1986). In the monoclinic form it has a density of 6.1 g cm^{-3} . The cubic phase has a face centered structure with a density 6.09 g cm^{-3} . In pure ZrO_2 , the monoclinic phase is stable up to about 1170°C, where it converts to tetragonal. At 2370°C, a cubic phase is formed, stable up to a melting point of 2680°C. The materials used in practice contain various stabilizing additives (various oxides, the most common is yttria) and the stability areas of the individual phases vary considerably.

The conversion of tetragonal to monoclinic modification is associated with a volume increase of about 5%. If the ceramic contains grains of metastable t - ZrO_2 which are capable of martensitic transformation, during crack propagation the tensile stresses at its face cause a $t \rightarrow m$ transformation and energy is absorbed in the transformed zone. This process inhibits crack propagation and improves the mechanical properties of the material (Garvie *et al.*, 1975).

Typical high strength, fracture toughness and chemical stability allow its use in extreme conditions (Garvie *et al.*, 1975). It is chemically resistant to temperatures above the melting point of Al_2O_3 . It has low thermal conductivity (five times lower than Al_2O_3). It resists metal melts and has high abrasion resistance. It is used in oxygen sensors and as a susceptor (heating element) in high-temperature induction furnaces, where it can operate in oxidizing atmospheres at temperatures above 2000°C. It is attractive for nuclear energy, where it is used in inert matrices for the storage of plutonium and nuclear waste. Other applications include cutting tools, seals and pistons in pumps for chemically aggressive and abrasive suspensions, bearings, biomedical implants (e.g., dental prostheses, knee and hip joints) (Garvie *et al.*, 1984), as well as thermal barrier coatings (TBC).

The framework of usability of often used tetragonal zirconia ceramics stabilized by 3% Y_2O_3 (3Y-TZP) has been studied in great depth as part of the effort to use these materials for biomedical implants, materials for teeth and joints (Cales and Chevalier, 1998;

Marro *et al.*, 2009; Hvizdoš *et al.*, 2009, 2010a; Chevalier *et al.*, 2020). 3Y-TZP is prone to low-temperature degradation (LTD), where under certain circumstances in presence of humidity at room and slightly elevated temperatures metastable tetragonal zirconia crystals can spontaneously transform to the monoclinic form, which leads to microcracking and negatively influences its bulk properties. The effect of LTD on the wear resistance was mapped using scratch testing (Hvizdoš *et al.*, 2009), as well as tribological analysis in combination with wide range of loads in speeds (Hvizdoš *et al.*, 2010a). The results of tribological tests were correlated with observations of microstructure and damage régimes, and conditions of 'mild-to-severe' wear transitions for zirconia/zirconia contact were identified (at 10 loads it was at speed approximately $0.1\text{--}0.2\text{ m s}^{-1}$) (Hvizdoš *et al.*, 2010a). It was found that fully tetragonal zirconia is more resistant than the degraded material, and at the same time it was shown that in quite a wide range of conditions only small levels of $t \rightarrow m$ transformation takes place due to mechanical stresses.

In zirconia-CNF composites a strong effect of the filler has been observed (Hvizdoš *et al.*, 2010b), both on the friction coefficient and on the wear rates, (Fig. 1). Microscopic observations of the worn surfaces of ZrO_2 - CNF composite materials reveal pulled-out CNF and indicate the presence of a tribofilm of dispersed graphite and crushed carbon nanofibers. These processes significantly reduce the values of the coefficient of friction, even in the case of a relatively low amount of carbon (1.07 wt%). The lubricating effect induced by the rolling of carbon filaments in the area of contact was not observed (Hvizdoš *et al.*, 2010b). However, the imperfections of the microstructure of the composites also lead to slightly higher specific wear rates which increased by about 50% when compared to the monolithic 3Y-TZP (Fig. 1(b)).

Nitrides – Silicon Nitride Based Ceramics

Silicon nitride (Si_3N_4) is a human-synthesized compound. The bulk material is characterized by a unique set of excellent properties. It has a relatively high strength and fracture toughness, low density (3.2 g cm^{-3}), and, thanks to the SiO_2 surface layer, good resistance to corrosion and oxidation at room and elevated temperatures. Due to the low coefficient of thermal expansion ($3.1\text{--}3.6 \times 10^{-6}\text{ K}^{-1}$ from room temperature up to 1000°C), it also has relatively good thermal shock resistance. The most desirable microstructure, typically used in industrial applications consists of fine $\alpha\text{-Si}_3\text{N}_4$ grains and larger $\beta\text{-Si}_3\text{N}_4$ grains with high aspect ratio. It has high strength and improved fracture toughness (Morrell, 1985). Silicon nitride is a relatively expensive material, but in applications where its excellent properties are combined with its durability and low maintenance, it can also be very economically advantageous as it has excellent resistance to abrasion and erosion. High-quality silicon nitride-based materials have been developed for use in internal combustion engines for valves and cams, where they have proven very successful. Unfortunately, the cost of larger ceramic components has never been reduced enough to be used to make all-ceramic engines or turbochargers. However, high quality components can be manufactured and used in many applications under conditions of high mechanical or thermal stress or abrasion.

In general, the wear behavior of Si_3N_4 -based materials is reported to be controlled by the following mechanisms (Wang and Hsu, 1996; Dong and Jahanmir, 1993; Skopp *et al.*, 1995): (1) mechanically- or thermally-induced microcracking due to fatigue assisted stresses resulting from friction at high normal loads, (2) tribochemical reaction with water vapor at low temperatures and normal loads ($<400^\circ\text{C}$, $<10\text{ N}$) and (3) tribooxidation at temperatures that depend on the composition and nature of the intergranular phases, generally above 500°C (Balko *et al.*, 2014).

As silicon nitride, particularly in self-mated configuration, has relatively high friction (COF over 0.5), various strategies have been applied to lower its value.

When using CNTs as additives, a clear influence of their content on friction and wear was shown by Hvizdoš *et al.* (2011, 2012). For low CNT contents a high friction coefficient was maintained (Fig. 1(a)). It started to decrease only when the CNT fraction reached about 5 wt%. In Si_3N_4 -10% CNT, the COF values decreased to ~ 0.35 . The wear resistance in general decreased but in certain cases some sort of optimum was identified (Si_3N_4 -5% CNT), where the wear rate was the same as for monolithic silicon nitride, but with much lower coefficient of friction (Hvizdoš *et al.*, 2012).

A more efficient improvement seems to be the use of graphene nanoplatelets (Hvizdoš *et al.*, 2013; Llorente *et al.*, 2019; Puchý *et al.*, 2020). As can be seen from Fig. 1(a), even at low proportions (1 and 3 wt% GNP) there was no increase in the coefficient of friction and the wear rate decreased significantly (Fig. 1(b)), mainly due to the improvement of fracture toughness, (Hvizdoš *et al.*, 2013). Llorente *et al.* (2019) showed that at higher contents of GNP, friction can be decreased by 50% at intermediate and high loads. Also, wear resistance was shown to improve in such composites (by up to 63%) in a monotonic way with respect to monolithic silicon nitride. Here, a C-rich tribofilm with oxidized Si_3N_4 particles plays a protective and self-lubricating role (Llorente *et al.*, 2019). When testing Si_3N_4 - GNP composites at elevated temperatures ($300, 500, 700^\circ\text{C}$), the positive effect of GNP gradually disappeared, so that at 700°C the properties of the composites were comparable to the monolithic ceramics, (Balko *et al.*, 2014). On the other hand, it was also shown that even at these temperatures, the GNPs remained structurally and chemically stable and did not decompose within the matrix. It was also found that no transformation of $\beta\text{-Si}_3\text{N}_4$ to $\alpha\text{-Si}_3\text{N}_4$ occurred at any stage of the test, (Balko *et al.*, 2014).

The literature for composites based on silicon nitride generally agree very well (Belmonte *et al.*, 2013; González-Julián *et al.*, 2014) for Si_3N_4 - MWCNT/SWCNT, where the coefficients of friction in the range of stability had values of 0.22–0.24. Generally speaking however, in terms of reductions in friction coefficients, randomly distributed CNTs and GNPs are effective only at relatively high contents, 20% and more (Belmonte *et al.*, 2013; González-Julián *et al.*, 2014; Miranzo *et al.*, 2017).

The wear behavior of composites reinforced by hard nanoparticles has a character different from those reinforced with carbon. Tatarko *et al.* (2010) presented a thorough study of silicon nitride based nanocomposites sintered with a wide range of rare-earth oxides,

which were further doped with SiC nanoparticles and the interesting findings are here reviewed. Introduction of SiC nanoparticles into the silicon nitride matrix improves hardness, strength, resistance to creep, oxidation and corrosion of Si_3N_4 ceramics. [Tatarko et al. \(2010\)](#) further found that the wear resistance increased with decreasing size of rare-earth cations in the Si_3N_4 monoliths as well as the Si_3N_4 -SiC composite materials sintered with different rare-earth oxide sintering additives. The friction coefficient slightly decreased with decreasing ionic radius of RE^{3+} from 0.74 to 0.70 in the case of monoliths and from 0.71 to 0.64 in the case of composites for the materials sintered with La_2O_3 and Lu_2O_3 , respectively. Similarly, the specific wear rate decreased with decreasing ionic radius of RE^{3+} from $3.22 \times 10^{-5} \text{ mm}^3 \text{ N}^{-1} \text{ m}^{-1}$ to $1.15 \times 10^{-5} \text{ mm}^3 \text{ N}^{-1} \text{ m}^{-1}$ for the monolithic Si_3N_4 sintered with La_2O_3 and Lu_2O_3 , respectively, and from $1.91 \times 10^{-5} \text{ mm}^3 \text{ N}^{-1} \text{ m}^{-1}$ to $0.89 \times 10^{-5} \text{ mm}^3 \text{ N}^{-1} \text{ m}^{-1}$ in the case of composites doped with the same additives. The same study showed that friction coefficient as well as the specific wear rate of composites was always lower compared to the monoliths with the same sintering additives indicating the higher wear resistance of Si_3N_4 -SiC composites.

The bonding strength between Si_3N_4 grains and grain boundary phases increases with decreasing ionic radius of RE^{3+} . Therefore, the highest bonding strength in Si_3N_4 containing Lu_2O_3 as a sintering additive restricts pull-out of the individual silicon nitride grains during the wear experiment. This fact together with its highest hardness and fracture toughness values are the reasons why Si_3N_4 doped by Lu exhibited the best wear resistance among all studied monolithic materials, ([Tatarko et al., 2010](#)).

The addition of SiC nanoparticles to this class of materials led to lower fracture resistance. In spite of that, the composites exhibited higher wear resistance in comparison with that of monolithic Si_3N_4 . This is probably due to their higher hardness whose positive effect was more significant than the influence of the lower fracture toughness, ([Tatarko et al., 2010](#)).

The wear mechanisms and the tribological characteristics were almost analogous for the monolithic Si_3N_4 and the Si_3N_4 -SiC composite materials. The mechanical wear (micro-fracture) and tribochemical reaction were found as the main wear mechanisms for all the studied materials. With increasing wear resistance, the worn surface becomes rather smooth but adherent debris are still present. An addition of SiC into the Si_3N_4 materials results in a higher number of "islands" of coherent debris, which then leads to formation of the protective tribolayer. In addition, the highest amount of coherent debris was observed for the material with the highest wear resistance, i.e., for the composite sintered with Lu_2O_3 , ([Tatarko et al., 2010](#)).

More fractured areas and a higher amount of silicon nitride debris were observed for the specimens having lower wear resistance. Such fractured areas show a mixture of intergranular and transgranular failure modes in the worn surfaces. According to the mechanisms described by [Wang and Hsu \(1996\)](#), [Dong and Jahanmir \(1993\)](#), and [Skopp et al. \(1995\)](#) for wear of silicon nitride-based materials, cracks initiate below the surface and propagate assisted by fatigue effects in a mixed intergranular/transgranular mode leading to microscale delaminations and fragmentation.

The coherent layers formed on the wear surfaces contain large amounts of oxygen, meaning that the layers are composed mainly of the oxidation products of silicon nitride. The formation of oxide may be accelerated by the presence of small particles of silicon nitride formed by fracture under the high contact stresses at the wear interface. These particles have a high specific area, which would increase the amount of reaction products formed compared to a reaction with the bulk of the ceramic.

Unlike the CNT/CNF containing nanocomposites, where the secondary phases not only reduced the coefficient of friction but also lowered the wear resistance, incorporation of SiC nanoparticles left the coefficient of friction unchanged but improved the wear resistance. This suggests that further development has the potential to improve overall tribological performance of ceramic nanocomposites.

Additions of boron nitride particles allows the production of another very interesting class of wear resistant silicon nitride based composites ([Carrapichano et al., 2002](#); [Wei et al., 2006](#); [Kovalčíková et al., 2014](#)). Hexagonal boron nitride (hBN) is attractive for its lubricating effect, high hardness, and when used in an adequate form, e.g., flat platelets, it offers an improvement in fracture toughness. In [Kovalčíková et al. \(2014\)](#) it was found that small quantity of micrometer sized hBN can increase the fracture toughness of the composite by approximately 50% - from 5 up to $7.5 \text{ MPa m}^{1/2}$. Similarly as for CNTs, small amounts of well-integrated hBN platelets do not lubricate and consequently do not lower the COF. However, it was shown that Si_3N_4 with 1 wt% hBN the specific wear rate was lower by 78% compared to the monolithic Si_3N_4 . The main wear mechanism for Si_3N_4 -hBN composites is abrasion with micro-fracture accompanied by tribochemical reaction with surface oxidation.

Carbides I – Silicon Carbide Based Ceramics

Silicon carbide (SiC) is a hard material used in the ceramic industry for many years. Its α -phase, stable to high temperatures, is crystallographically hexagonal and forms when carbon and silicon come into contact at high temperature in a reducing atmosphere. Its high decomposition temperature (2700°C) predetermines it as a material useful for bearings or furnace components. Its very low coefficient of thermal expansion ($4 \times 10^{-6} \text{ K}^{-1}$) without phase transformations guarantees its high temperature stability and thermal shock resistance. Thanks to its high hardness it is used for cutting tools and as a grinding medium. However, due to its brittleness it is very difficult to machine and its mechanical reliability is low. For this reason, SiC based composites with enhanced fracture toughness and formability/machinability are being designed. Again, promising are the carbon phase fillers (CNT, GNP) ([Džunda et al., 2019](#); [Guo et al., 2019](#)), or incorporation of other carbides, e.g., TiN/C with high hardness ([Frajkorová et al., 2012](#); [Fides et al., 2017a](#)).

Silicon carbide-based ceramics generally show lower coefficients of friction than Si_3N_4 materials (see [Table 2](#) and [Fig. 1](#)). SiC-CNT composites exhibit very stable values of the coefficient of friction (0.3–0.4) regardless of amount of CNT, which is probably related to the firm anchoring of CNT in the SiC matrix ([Džunda et al., 2019](#)). As a result, they cannot be released into the contact zone and act as a solid lubricant. Similar behavior is typical in SiC – GNP, where friction even increased slightly with increasing carbon content (except for COF = 0.6 at the higher contents of C – above 5%), probably due to the coarse-grained

Table 2 Typical values of coefficient of friction of unlubricated ceramics at room temperature

Material	Coefficient of friction	references
Al ₂ O ₃	0.3–0.6	Bhushan (1999), Puchý <i>et al.</i> (2013)

structure and higher porosity (again for the higher contents). Regarding the wear resistance, it was shown that the good quality distribution and strong CNT bonds grown in-situ on SiC grains led to a very stable abrasion resistance of these materials. Similar behavior was observed for SiC – GNP, especially at low loads. Only at loads around 50 N at high contents (6 wt%) of GNP was the wear rate increased approximately twofold (Hvizdoš *et al.*, 2016).

In the case of SiC – TiN/C composites, at different loads from 5 N to 30 N, they behave very stably, with a slightly increasing coefficients of friction increasing from 0.29 to 0.32–0.39–0.50 (Fides *et al.*, 2017b). These composites also showed very stable wear behavior with low material loss values (about 10^{-6} mm³ m⁻¹ N⁻¹) for all materials up to relatively high loads (Fides *et al.*, 2017b). Their worn tribological surfaces are characterized by abrasion and fracture of the grains, facilitated by an intergranular type of failure, which was also observed in the analysis of mechanical and fracture properties (Fides *et al.*, 2017a). At higher wear loads, microcracks appear, forming mainly at a certain depth (typically around 5–10 μm) under the contact surface (Fides *et al.*, 2017b).

Carbides II – Boron Carbide Materials

Boron carbide (B₄C) is a relatively new industrial material. For the first time it was prepared only in mid-nineteenth century and its exact stoichiometry has been known only since 1934. It has a very high hardness. It is the third hardest known bulk substance after diamond and cubic boron nitride, with a hardness of 34 ± 4 GPa and Young's modulus 360–460 GPa (Sairam *et al.*, 2012). Its melting point is 2450°C and thermal conductivity 30 W m⁻¹ K⁻¹. Electrically, it is a semiconductor, like silicon carbide. Due to its advantageous properties its actual or potential applications include wear resistant components, aerospace materials, lightweight and bullet-proof armors, aerospace components, nuclear absorbers and control rods, etc. (Thévenot, 1990; Sedlák *et al.*, 2017a).

B₄C is a material with low sinterability. To facilitate its densification at lower temperatures and to enhance its mechanical performance (improve strength and fracture toughness), various additives have been tried, mostly boron, alumina, silicon, carbon, TiB₂, SiC, etc. (Kim *et al.*, 2000; Sedlák *et al.*, 2017a). The material can be prepared usually by hot pressing (HP) of very fine grain powders (<2 μm) at high sintering temperatures of 2100–2200°C, heating/cooling rates 10°C. min⁻¹ with typical dwell times of 15–45 min under 30–40 MPa. More recently graphene-based nanostructures attracted interest and are being adopted for use as fillers. In order to preserve their integrity, fast sintering methods are used such as spark plasma sintering (SPS) and flash sintering (FS) (Rehman *et al.*, 2014; Sedlák *et al.*, 2017a,b). To explore the possibilities of using the fast preparation procedures, Sedlák *et al.* (2017a,b) performed a series of experiments and made a comprehensive comparison of B₄C–GNP composites prepared by HP, SPS, and FS, with the total time of sintering being 7.5 h, one hour, and one minute, respectively.

In B₄C–GNP, with GNP contents from 0 up to 6 wt%, prepared by HP and SPS the final densities were about 99% and more, values consistent up to high amounts of GNPs. Flash sintering resulted in densities 91%–95%, when higher amounts of carbon actually led to higher density showing the benefit of densification promoting role of present carbon. Typically, GNPs have preferential directionality because in all methods one axis pressing is used, but the GNP/BN grains bonding is very good, (Kovalčíková *et al.*, 2016; Sedlák *et al.*, 2017a). Hardness is governed by residual porosity and basically independent of the GNP content. In the fully dense materials, the hardness is 20–24 GPa, while in the FS materials it was 15–17 GPa (Sedlák *et al.*, 2017b). The fracture toughness, however, showed clear benefit of the GNP presence. It steadily increased from 3 MPa m^{1/2} for boron carbide up to 4.5 MPa m^{1/2} for the composite with 6 wt% GNP (Kovalčíková *et al.*, 2016). Here, the typical toughening mechanisms by thin platelets were identified. Tribological testing showed that the coefficient of friction is similar both in monolithic B₄C and the composites (0.4–0.6), but the wear rates showed benefit of the improved fracture toughness of GNPs containing composites. The wear was typically severe but W decreased from 1.5×10^{-5} mm³ N⁻¹ m⁻¹ for monolithic B₄C by about 50% for B₄C – 6 wt% GNPs (Sedlák *et al.*, 2017b). As is typical in oxides and nitrides, also in B₄C based materials do tribochemical reactions occur at higher loads and higher temperatures and oxide layers, in the form of SiO₂ islets, are formed on the wear track surface (Sedlák *et al.*, 2017b).

Borides – Titanium-Diboride Based Ceramics

The titanium diboride ceramic is very hard (25 GPa), wear resistant and is a high temperature stable material with high elastic modulus. It is also electrically (resistivity $13 \times 10^{-8} \Omega \text{ m}$) and thermally ($64 \text{ W m}^{-1} \text{ K}^{-1}$) conductive. These properties are useful for a number of applications like cutting tools, wear-resistant parts for demanding conditions, armors, turbine blades, etc. It is, however, poorly sinterable and to achieve a sufficient density, high sintering temperatures and long dwell times have to be used. Such conditions result in grain growth, which causes a decrease of mechanical properties like fracture toughness and strength (Sánchez *et al.*, 2000; Wang *et al.*, 2002). Therefore, much research is aimed at the investigation of titanium diboride composites particularly with metals that could improve sinterability and fracture resistance. With the addition of metallic binders, the fracture toughness of TiB₂-based materials increased from 3 to 5 up to 6–12 MPa m^{1/2} thanks to improved plasticity and crack bridging toughening (Sánchez *et al.*, 2000; Chlup *et al.*, 2015; Fu and Koc, 2018a,b). Because of excellent chemical compatibility, TiB₂-Ti materials are considered very promising also for wear applications. Puchý *et al.* (2019) prepared a series of TiB₂ ceramics and TiB₂-Ti composites by SPS. They show that the high speed of the process prevented the significant grain growth. Moreover, whereas in the monolithic TiB₂ the densification starts at 2100°C, in the Ti containing composites it starts already at approximately 1495°C and relative density above 98% can be achieved. Adding of the metal lowered hardness but increased fracture toughness of the composites. Tribological studies show that for monolithic TiB₂ the friction coefficient is stable (0.5–0.6) for various load values and wear rates increase with increasing load – from 6×10^{-6} up to $17 \times 10^{-6} \text{ mm}^3 \text{ N}^{-1} \text{ m}^{-1}$ for loads from 1 N up to 10 N. Adding Ti improved the tribological performance, where the best was achieved with the TiB₂ with 20% Ti (Puchý *et al.*, 2019). In this case the friction coefficient decreased with increasing load (from 0.8 down to 0.3) and similarly specific wear rate decreased from 2×10^{-6} down to $0.66 \times 10^{-6} \text{ mm}^3 \text{ N}^{-1} \text{ m}^{-1}$. The microscopic observation of the wear tracks showed that in the monolith damage in the form of scales, grooves, scratches and microcracks were dominant. These suggest that adhesion and abrasion by plowing are the main damage mechanisms. The worn surfaces of the composites were flatter, smoother and less scaly. The damage was mostly self-polishing abrasion (Puchý *et al.*, 2019).

Another approach to improve the sinterability but without the softening caused by a metal is the use of SiC, which additionally can increase hardness, fracture toughness and oxidation resistance (Zhao *et al.*, 2014). Kovalčíková *et al.* (2020) also studied the influence of GNP additions to TiB₂-SiC composites on the wear resistance. They found that the presence of SiC (up to 25 wt%) improved the flexural strength from 500 MPa up 601 MPa. Then, addition of GNPs, from 1 to 10 wt% further increased the strength up to 673 MPa. Regarding the tribological properties, additions of SiC did not influence the COF which was 0.50–0.55. Addition of higher amounts of GNP (10 wt%) was necessary to decrease the COF down to 0.47. On the other hand, all GNP containing composites showed higher wear resistance. The specific wear rate of TiB₂-20% SiC was $6 \times 10^{-6} \text{ mm}^3 \text{ N}^{-1} \text{ m}^{-1}$ while that of TiB₂-20% SiC – GNP was around $10^{-7} \text{ mm}^3 \text{ N}^{-1} \text{ m}^{-1}$ for 1–10 wt% GNP at lower loads. The wear mechanism is similar for all TiB₂-SiC and TiB₂-SiC-GNP materials, dominated by abrasion and tribochemical reaction with formation of SiO₂-TiO₂-C based tribofilm (Kovalčíková *et al.*, 2020).

High Entropy Ceramics

In recent years a very promising new class of ceramic materials with unusual crystallographic structures have come to focus (Castle *et al.*, 2018; Dusza *et al.*, 2018). These so-called high entropy carbides (HEC) contain typically four transition metal ions in a carbide superlattice (Castle *et al.*, 2018). Their structure is non-stoichiometric and is slightly distorted over short distances but well-ordered on longer ones with strong ionic bonds (Csanádi *et al.*, 2019). Such crystallography leads to extremely high stiffness. The HECs were synthesized only in small volumes and until now there have not been reports of their tribological properties. However, it has been shown that their mechanical performance (hardness, strength) is far superior (Castle *et al.*, 2018; Csanádi *et al.*, 2019) to the typical ceramics and ceramic based composites and they are expected to possess also excellent wear resistance over a wide range of conditions.

Summary

Advanced dense structural ceramics with high hardness are excellent materials for tribological applications. Their wear resistance is typically very high, and under controlled circumstances, in the mild wear regime, their worn surfaces are smooth, often with a polished appearance, without microcracking. When reduction of dry friction is necessary, adequate composites can be designed. The most popular approaches are introduction of hard nanoparticles that could increase hardness and fracture toughness, and/or new carbon nanoobjects, which are expected to improve fracture toughness and also act as solid lubricants.

As regards the influence of carbon nanotubes, nanofibers, and graphene platelets, tribological analyses have shown a positive influence of their presence in the microstructure. Quite low contents of CNFs (approximately 1 wt%) is enough to decrease the friction coefficients of zirconia/zirconia and zirconia/alumina contacts, from 0.45 down to 0.2, thanks to the creation of a carbon rich tribofilm that works as a solid lubricant. CNTs are less effective and to achieve similar result high amounts are necessary. The coefficient of friction does not change easily in these composites, and in the mild wear regime it remains stable during the tests, only at higher loads and severe wear regime does the friction decrease. The wear resistance then in general decreases but in certain cases some sort of optimum can be found. In the case of GNP, if these are properly distributed in the matrix, the benefit in increasing abrasion resistance due to improved fracture toughness, even at elevated temperatures, has proven to be clear.

In non-oxide ceramics, such as nitrides, carbides, and borides, tribochemical reactions occur at higher loads and higher temperatures and oxide layers tend to form on the worn surfaces, most often in the form of silica islands (Balko *et al.*, 2014; Džunda *et al.*, 2019; Kovalčíková *et al.*, 2020). In composites with CNT and GNP grown in-situ (Hussainova *et al.*, 2016; Džunda *et al.*, 2019), nanotube or platelet agglomeration, so often observed in conventional hot-pressed samples, can be significantly suppressed, and the filler distribution is more homogeneous. Such efficient distribution in the matrix contributes to better compaction of the composites and to higher values of both mechanical and tribological properties.

Wear and Erosion Resistant Ceramic Coatings

František Lofaj, Institute of Materials Research of the Slovak Academy of Sciences, Košice, Slovak Republic

Marián Mikula, Comenius University in Bratislava, Bratislava, Slovak Republic

Introduction

Wear and erosion are the damage phenomena occurring at the contacting surfaces in mutual motion and resulting in gradual removal of part of a material from the contact area. They are closely related to friction, plasticity, fracture and other damage mechanisms occurring in the localized contacts which are subjected to relatively high stresses. Excessive material removal due to abrasion, erosion, corrosion and other mechanisms or their combinations result in a degradation of materials used for the structural components practically in all fields of industry and very often determine the lifetime of the corresponding products. In industry, around half of the wear losses can be attributed to abrasion and almost one tenth to erosion. The annual economic losses due to wear and corrosion in the USA already in early 90s were estimated to exceed 300 billion USD (Cox, 2001). More recent calculations on the global energy losses due to friction, which is closely related to wear, showed that friction has also extremely high economic impact. For example, the energy consumption in heavy-duty road vehicles and buses due to friction in engines, transmissions, tyres, auxiliary equipment, and brakes was estimated to be around 33% of the fuel energy. A reduction in friction may result up to a 2.5 x improvement in fuel economy with corresponding environmental benefits (Holmberg *et al.*, 2014). Analogous calculations in paper mill industry showed that the energy losses are in the range 15%–25% of total energy consumption (Holmberg *et al.*, 2013). Since wear and friction are surface related phenomena, the application of relatively thin low-friction coatings with much higher wear resistance is one of the most effective ways (besides lubrication which is not a subject of the current work) to reduce the wear and friction of the primary materials. This approach brings number of technical and economic benefits, especially due to the possibility to use “cheaper” basic materials which can achieve desired or better performance, extended lifetime and higher reliability due to better properties of the coating. On the other hand, a large number of challenges has to be solved and requirements fulfilled to guarantee the benefits from relatively thin layers subjected to the same or even higher loads than the original uncoated components. The necessary requirements for wear resistant coatings strongly depend on the type of loading regime in the contact area. Holmberg and Matthews (2000) proposed the following modes of tribological contacts: static contact stresses, sliding, surface fatigue, fretting, abrasion, impact and chemical dissolution. Regardless of the contact mode, the universal requirements to all coatings involve sufficiently high hardness and toughness combined with high adhesion, cohesion strength and low friction. The requirements specific for the particular contact mode include coating thickness, load support, proper elasticity, surface finish, etc. However, some variations in properties are possible even within each mode depending on the wear process and loading conditions. In the case of adhesive wear, hardness would be the main parameter whereas in the case of abrasive wear, higher toughness, adhesion and thickness would be required from the coatings, especially at higher loads. The properties necessary for erosion resistance also vary from hardness at low impact angles to hardness, toughness and good adhesion at high angle impact. Obviously, the selection of the coating providing the best wear and erosion resistance in each specific application would be limited not only by the determination of the material system but also by the understanding of the wear and friction mechanisms and their relationships to the coating properties as well its structure and as deposition conditions required for their achievement. Thus, the basics of tribology including dry wear and friction mechanisms, the main properties controlling wear and erosion resistance and the ways of their measurement are described in the first part of this chapter. The second part focuses on the deposition methods of PVD coatings exhibiting mechanical properties desired for wear and erosion resistant coatings by means of formation of nanocomposite structures. The work is intentionally limited to relatively thin PVD coatings. The detail information on the thick wear resistant coatings prepared by various spraying and electro/electroless plating technologies can be found elsewhere (Wolfe *et al.*, 2006; Fauchais *et al.*, 2011; Kuroda *et al.*, 2011).

Introduction to Tribology

Friction, wear, corrosion, erosion and related damage mechanisms as well as lubrication are the subject of tribology – “the science of interacting surfaces in relative motion and practices related there to” (Oberle, 1951; Archard, 1953; Czichos, 1978; Bhushan and Gupta, 1991; Hutchings and Shipway, 2017; Holmberg and Matthews, 2009; Bhushan, 1999; Bhushan, 2000). The word “tribology” originates from Greek “tribos” which means “rubbing” (Archard, 1953). Friction and wear are the consequences of complex interactions and processes involved in the contacts of two mating surfaces. The result of these interactions is determined by the conditions of mechanical loading (sliding, rolling, mixed movement, etc.), properties of each material of the tribocouple (especially hardness, elastic modulus, toughness and their ratios between coating and the substrate), surface conditions in the tribocontact (e.g., roughness) and often also by the environment (and related oxidation resistance, etc.). A brief description of such complex processes in this chapter requires certain simplifications. Therefore, sliding and rolling friction is considered at first as the primary process in which no material removal is involved. Then, wear mechanisms related to the damage resulting from friction forces and resulting in the material removal are described. Erosion is considered to be a specific mode of wear caused by impingement of solid particles, liquid drops or gas bubbles.

Friction

Friction in sliding motion is defined as a tangential resistance to relative motion of contacting bodies (Hutchings and Shipway, 2017; Holmberg and Matthews, 2009). The degree of friction is measured by a dimensionless coefficient of friction (COF), μ , which corresponds to the frictional (tangential) force F_f divided by normal load F_n on the contact (Fig. 1)

$$\mu = F_f / F_n \quad (1)$$

The Eq. (1) is called the first law of friction and means that the friction force is proportional to the loading force. However, friction can be considered also as a mechanism of energy dissipation and in that case, μ can be defined as a ratio of energy loss due to friction, W_f , to total energy in the system, W

$$\mu = W_f / W \quad (2)$$

However, for the development of physical models of friction, the second law of friction is more important. It says that the coefficient of friction does not depend on the contact surface area, A_n (see Fig. 1). The reason is that the contact surface is never absolutely flat, surface undulations and asperities are always present. Thus, the contact surface A_n is only apparent, true contact and load bearing area is limited to the contacts among the asperities. This contact area is several orders of magnitude smaller than A_n (Fig. 2). The macroscopic normal force F_n is applied to these highly localized asperity contacts and the local stresses there are subsequently much higher than the average stress calculated for A_n surface area from normal load F_n . As a result, asperities in the contacts are immediately elastically and even plastically deformed (in the case of brittle material, localized fracture can occur) and the contact area becomes A_r . It is controlled by the lower yield strength of one of the materials in the tribocouple. Since the area A_r is still approximately three orders of magnitude smaller than A_n , there is no direct correlation between friction and A_n .

The third law of friction states that the coefficient of friction does not depend on the sliding speed. However, it is in contrast with the existence of a static coefficient of friction when the friction force for the initiation of sliding at the same normal load is higher than the force during stable sliding at various speeds. The reason is that in static case, A_r can increase (e.g., due to creep) over time.

The friction forces were originally attributed only to the adhesion between asperities and to the shear strength of their connections during sliding (Bowden and Tabor, 1950). However, plastic deformation of the asperities in the contacts and plowing effects resulting from the presence of debris and/or third bodies may also contribute to friction forces and energy dissipation during sliding. Thus, the coefficient of friction consists of:

- adhesion, involving breaking of the adhesive bonds between the asperities;
- plowing, corresponding to the resistance to deformation when a harder counter-surface moves through a softer material;
- deformation (elastic and plastic) and
- other possible components.

Fig. 1 Schematic of the forces in a sliding tribo-couple subjected to a normal force of F_n and the contact surface, A_n . The friction force F_f is proportional to F_n but the coefficient of friction does not depend on the contact surface A_n .

Fig. 2 Schematic of the microscopic contacts between two mating surfaces during normal loading (the scale in vertical direction is unproportionally magnified) – a; the formation of the true contact area A_r among asperities after elastic and plastic deformation during sliding.

The adhesion component or mechanism of friction is proportional to the interfacial shear strength of the contacts between asperities (Bowden and Tabor, 1950; Rabinowicz, 1965) and surface energy of the contacting tribo-couple rather than on the properties of the individual materials. In the real situation, adhesion can be affected by the reactions with the environment and formation of transfer layers. Plowing component appears when one of the materials in the tribo-couple is harder and its asperities penetrate and plow into a softer material. Besides individual asperities, plowing may occur also by the debris originating from previous wear events. Plowing means that the counter-surface is deformed elastically and plastically, both of which result in energy dissipation. Because the elastic part is recoverable, the most of the energy losses have to be related to plastic deformation. The deformation component of the coefficient of friction is determined by the hardness and elastic moduli of the coating, substrate and the counterpart as well as by their shear strength and shear strength of the interface (Heilman and Rigney, 1981). The plowing mechanism is controlled by the resistance to elastic and plastic deformation and the size and geometry of the asperities and/or plowing particles. Additional energy consuming contributions due to elastic hysteresis losses in some viscoelastic surfaces can arise from cyclic deformation and high internal damping. Holmberg *et al.* (2007) suggested that *hysteresis* is an alternative basic mechanism of friction besides adhesion and plowing. A hysteresis mechanism was attributed to the resistance originating from the continuous elastic deformation in the contacts of the moving surfaces whereas plastic (and elastic) deformation was assigned to plowing. However, regardless of the earlier and current classifications, the basic friction mechanisms during sliding remain adhesion, plowing (with plastic deformation) and elastic deformation (hysteresis).

The friction forces occurring during rolling are typically much smaller than during sliding. However, rolling involves also varying amount of sliding, referred to as *slip*. It is a consequence of finite contact area due to elastic deformation of contacting bodies during rolling. Because the radii of the different points in the contact surface are different, unequal tangential displacements leading to interfacial microslips are introduced. Adhesion mechanism in rolling may play only a minor role because of the separation of the contacting surface at the trailing edge occurs in tension rather than in shear. Obviously, the mechanisms resulting from elastic hysteresis and plastic deformation in the rolling contact may also be involved. Further details on rolling mechanisms can be found in (Bhushan and Gupta, 1991).

Wear

In contrast to friction when no material removal occurs, wear is defined as a process of the detachment of material from one or both contacting surfaces moving over another (Bhushan and Gupta, 1991; Hutchings and Shipway, 2017; Holmberg and Matthews, 2009; Bhushan, 2000). Obviously, the main difference is that besides conventional mechanisms considered in friction, fracture processes leading to the detachment of material are involved. Fracture in this case means the loss of cohesion via cracking producing debris released from the surface instead of separation of a body into two or more pieces common in the case of brittle bulk material fractures. The fracture events in the coating/substrate systems during wear may principally occur either at the top surface of the coating, within the coating, along the coating/substrate interface or in the substrate. The rate of the material removal resulting from wear is quantified using universal wear rate parameter K defined as a volume of the material, V , removed from the contact surface under the normal load, F_n , after moving for a distance, l

$$K = K'/H = V/(F_n l), \quad (3)$$

where K' is a constant and H is the hardness of the material. The physical meaning of the wear rate K is the worn volume divided by the mechanical energy introduced into the contact. The energy input corresponds to the load and distance which is equal to the load, velocity and time of the mutual movement. The commonly used dimension of K is ($\times 10^{-6}$) mm^3/Nm .

The wear mechanisms may be classified in several ways depending on the type of relative motion (sliding, rolling, fretting, impact, etc.) and type of wearing contacts (single phase with solid, liquid or gas phase) but the most common approach is based on the dominant wear mechanism. They include adhesive (also called galling or scuffing) wear, abrasive wear, fatigue, chemical (corrosive) wear mechanisms (Fig. 3).

Sometimes, fretting wear, erosive wear by solid particles, fluids or cavitation and electric-arc induced wear are considered as independent mechanisms (Holmberg and Matthews, 2000; Bhushan and Gupta, 1991; Holmberg and Matthews, 2009). However, when the focus is made on the way material removal takes place, the principal wear mechanisms can be reduced to only three cases (Holmberg *et al.*, 2007):

- Adhesion + fracture – it is typical for the tribo-pairs with identical or similar mechanical properties. The debris is formed due to adhesion generated tensile and shear stresses exceeding material strength. The wear rate in this case can be reduced by the reduction of the normal load and/or by using materials with higher strength.
- Abrasion + fracture – it is applicable to the systems with different hardness or when additional hard particles are introduced in the tribo-pair which result in severe plowing. The debris results mainly from excessively high shear stresses (exceeding the strength of the material) and subsequent cracking and detachment when hard particle or asperity moves through softer counterpart. The rate of abrasion can be reduced using harder materials or by load reduction.
- Fatigue + fracture – this mechanisms occur in the materials prone to cyclic fatigue. Crack nucleation, propagation and debris formation result from cyclic loading generating (mainly compressive) stresses exceeding the fatigue limit. This mechanism has usually two phases. In the first phase, surface structure and properties are modified without cracking. It occurs in the second phase when modified material cannot withstand the stresses resulting from damage accumulation during previous cyclic loading.

Fig. 3 The main wear mechanism (a) – adhesive, (b) – abrasive, (c) – fatigue, (d) – chemical wear. Reproduced from Holmberg, K., Matthews, A., 2009. *Coatings Tribology: Properties, Techniques and Applications in Surface Engineering*, third ed. Amsterdam: Elsevier Science.

Tribochemical wear, including corrosive wear, is not regarded as an independent mechanism because the corresponding chemical reactions modify the surface composition and properties of the top layer, but the removal of the material occurs via the same three above mentioned mechanisms. Thus, the chemical changes may be considered only as an additional parameter influencing the basic wear mechanisms.

Erosion

Erosion is a wear mode when the removal of the material occurs due to the impact of the solid particles, liquid drops or gas bubbles onto the surface of the material. When hard solid particles carried out by carrier gas or fluid impact the surface of a slightly softer coating with sufficient energy (Fig. 4), a part of the surface material (coating or coating/substrate) is removed analogically to sputtering. Note that the attention in the current work is paid to the erosion by solid particles and the case of erosion by cavities (bubbles) formed in the unstable liquids and imploding against the surface of the solids is not considered. Although the erosion wear by solid particles causes serious concern also in dentistry (Imfeld, 1996) it is highly relevant to energy and engineering industry, e.g., in moving blades, valve shutters and pipe bends etc. in the pipelines for coal transportation and hydrogenation systems, coal and hydraulic turbines, catalytical cracking of oil, heat exchangers, etc. Typical examples of deleterious influence of erosion in engineering represent the wear of blades and vanes in the turbine engines and blades of the helicopters by sand. On the other hand, erosion is successfully exploited in sand blasting, erosive drilling and abrasive deburring (Finnie, 1995).

The erosion by solid particles differs from abrasion by plowing of hard particles by the forces resulting in their movement. In the case of abrasion, the contact pressure depends mainly on the normal load whereas in erosion, the particles are driven by drag of the flow of surrounding medium, gravitational force as well as inter-particle forces and contact forces at the surface (Bhushan and Gupta, 1991; Holmberg and Matthews, 2009).

The erosion rate depends on a number of factors related to both eroding particles and eroded material as well. The main parameters on particle side involve type, number, mass and velocity (energy) of the particles and their angle of incidence. The

Fig. 4 Schematic of the erosion wear by solid particles.

Fig. 5 The schematic comparison of the angular dependencies of erosion rates in ductile and brittle materials.

main properties on the eroded material side are toughness and hardness. In the case of erosion of ductile materials under normal incidence, the maximum erosion ratio, defined as mass eroded material to the mass of particles impacting the surface, is proportional to the density of the particles, square of their velocity and inversely proportional to the hardness of the eroded material. This dependence is similar to that of abrasive wear. The decrease of the angle of incidence from normal increases the erosion rate and the maximum is achieved at around 20° – 30° (Fig. 5). Such behavior can be explained by considering cutting and deformation as two competing mechanisms involved. At small angles of incidence, a cutting mechanism involving plowing and/or fragmentation of the surface is dominant. At normal incidence, deformation mechanisms involving formation of pile-ups (lips) at the edges if the indents, their flattening and gradual removal by subsequent impacts, would dominate. In contrast to ductile materials, brittle materials exhibit the maximum erosion ratio at normal incidence (see Fig. 5). In that case, severe cracking results from the formation of surface ring and conical cracks and/or lateral and median cracks similar to those reported under single indents during hardness tests (Lawn and Swain, 1975). When these cracks interact with the surface, material is released from the surface in the form of chips or lips. At larger angles of incidence, the above mechanisms are suppressed and the erosion rate decreases (Finnie, 1995).

The erosion rate is usually determined from the data obtained from the volumes of the craters produced using rubber wheel abrasion tests at higher loads and/or in micro-abrasion tests at low loads. In the first case, dry sand is continuously supplied into the contact area between a rotating rubber lined wheel pressed against the tested sample under a constant load. This type of testing is normalized in an ASTM standard G-65. In the case of micro-abrasion tests under low loads, liquid slurries of abrasive media (e.g., SiC powder with the particle size in the range of several micrometers) are introduced between the sample and the rotating ball. Such configuration corresponds to the calotester but specialized devices can be used when wider load range is required.

Wear Reduction

The above considerations of classification, models and wear and erosion mechanisms indicate that material removal is a complex process consisting of various deformation and fracture events occurring simultaneously. The ways to reduce wear and erosion depend on the control of the testing conditions as well as of the main properties of the tested coating. As discussed earlier, adhesive wear during dry friction is inversely proportional to the hardness of the coating. Obviously, additional properties involving toughness to reduce fracture and subsequent plowing, stiffness to provide sufficient bearing capability, the counter-part with low tendency to form solution with the coating material, sufficient adhesion, etc. are also important. In the case of abrasive mechanisms, hardness is also the main parameter but a large number of additional parameters and concepts including elastic modulus, ratio of hardness to modulus, strain energy, plastic work etc. have also been considered to find out direct correlations

with the wear resistance (Bhushan and Gupta, 1991; Hutchings and Shipway, 2017; Holmberg and Matthews, 2009; Bhushan, 1999; Kramer, 1983; Leyland and Matthews, 2000, 2004). Because fracture is the critical process in wear, the combination of toughness enhancement (= higher ductility) and higher hardness (= low ductility) is highly desirable but difficult to achieve. For the reduction of erosive wear by solid particles, high resilience of the surface (determined by the ratio of tensile strength and elastic modulus and corresponding to the amount of energy absorbed before deformation or cracking occurs) simultaneously with high hardness and toughness are of principal importance (Bhushan and Gupta, 1991; Kramer, 1983; Leyland and Matthews, 2000, 2004). Again, high hardness and toughness are the primary properties to achieve high wear resistance. On the other hand, the ratio of hardness to elastic modulus, H/E , was found to correlate with wear resistance much better than just hardness (Leyland and Matthews, 2000, 2004). The ratio H/E is also a part of the plasticity index, which is used for the calculation of the limit of elastic behavior in surface contacts (Musil, 2000). Moreover, the yield pressure in a rigid ball on a plate is proportional to the H^3/E^2 ratio (Leyland and Matthews, 2000, 2004) and it is a part of the relationships defining toughness (Lawn and Swain, 1975; Musil, 2012; Musil and Jirout, 2007; Musil, 2012). Thus, the primary requirements for the suppression wear can be reduced to the increase of H/E ratio, because it would result in the reduction of the deformation as well as fracture in the contacts of two moving bodies. $H/E \geq 0.1$ was proposed as a limit for achieving proper combination of hardness and toughness. The ratio can be adjusted by the reduction of elastic modulus rather than by hardness increase via structure modification, especially in the coatings with nanocomposite structures (Leyland and Matthews, 2000; Musil, 2012; Musil and Jirout, 2007; Musil, 2012). At the same time it is clear, that despite H/E ratio is important and very convenient parameter, which can be relatively easily obtained from nanoindentation measurements, it is a simplification relating to material side only. It definitely cannot provide absolute values of wear rates depending on the geometry, loading conditions, real stress distributions, environment, contamination and many other factors.

Structure and Property Control in Hard Coatings

From the viewpoint of mechanical properties, wear and erosion resistant coatings have to exhibit high hardness combined with reasonable elastic modulus and sufficient toughness. To achieve these properties, the requirements to possible candidate materials for coatings can be divided into two levels.

The first level, intrinsic, is given by the nature of the chemical bonds, the electron configuration of the atoms and their mutual interactions. The hard coatings are most often binary, ternary or quaternary ceramic materials based on borides, carbides, nitrides or oxides in combination with transition metals of group IIIB to VIB and optionally containing semi-metals e.g., silicon (Table 1). Usually, the hard coatings are a mixture of metal, ionic or covalent bonds, some of which predominate and determine the properties of the material. For example, the transition metal nitrides have a rather metallic character which is clearly manifested by excellent electrical conductivity, good adhesion and lower hardness compared to ion-bonded coatings. However, they can plastically deform, i.e., they have higher ductility. On the other hand, coatings where the covalent or ionic character prevail (e.g., borides, carbides) are harder, have higher thermal stability and are chemically inert to various aggressive environments. They are however, brittle and almost unable to plastically deform.

The second level is extrinsic, that is, the properties of the hard coatings are controlled by the nature of their structure (amorphous, nanocrystalline, nanocomposite - a combination of nanocrystalline and amorphous phases), grain size, point defects, dislocations, and internal stresses in the crystalline lattice. The extrinsic character can be influenced by changing the deposition parameters during growth of hard coatings. Obviously, the intrinsic properties can be achieved only via selection of proper material system for the coating but the intrinsic properties, including H/E ratio and other properties, can be controlled via structure modification during deposition. Therefore, PVD deposition methods and resulting structure modifications as a way to control the properties required for high wear and erosion resistance of ceramic coatings is discussed elsewhere.

PVD Methods for the Preparation of Hard Coatings

Physical vapor deposition (PVD) methods include a group of deposition techniques where the growth of hard coatings typically occurs in plasma assisted processes in an inert (Ar) or reactive (e.g., Ar + N₂) atmosphere. These are mainly cathodic arc evaporation (ARC) and magnetron sputtering. ARC dominates the industry but in recent years there has been an increase in magnetron sputtering and its progressive modifications (High Power Impulse Magnetron Sputtering – HiPIMS).

ARC technology is based on local evaporation of the target using an electric arc (high currents up to ~150 A, low voltages up to ~80 V). During the deposition, an extremely overheated (15,000°C) cathode spot develops on the target surface which in a short period evaporates the target material, forms a crater and moves to a new surface. The process is accompanied by high ionization of the evaporated atoms (80%) and by the formation of macroparticles that build into the growing films and roughen their surface. During magnetron sputtering, a glow discharge (low currents up to tens of amperes and high voltages of hundreds of volts) is ignited where ionized gas atoms (Ar, N₂, O₂) are accelerated to the target surface and subsequently eject target atoms that are delivered to the substrate and form the coating. The advantage of magnetron sputtering compared to ARC is the reduction of roughness and the absence of macroparticles. In general, both PVD technologies allow for great variability in the chemical and phase composition of the coatings, basically any metal, alloy and ceramic targets can be used and high temperature phases are

formed in the coatings at low deposition temperatures or on unheated substrates. By combining different targets, it is possible to create multi-layer systems, superlattices, nanocomposites, etc. After application of the hard film, no further machining of the component surfaces is required.

The main role in the formation of hard coatings by PVD technology is played by two basic processes by which the nature of the structure and the resulting mechanical properties can be controlled: (1) the energy delivered to the growing film and (2) the mixing processes (Musil, 1992).

Energy Delivered to the Growing Film

Deposition of hard coatings by PVD methods is accompanied by low energy ion bombardment with values of ions energy in the range of tens to hundreds of electronvolts (eV), when positively ionized working gas particles or ions formed from target atoms bombard the surface of the coating. Since the ions are very small in size, the transfer of their kinetic energy E_{bi} into the growing film and its heating takes place at the atomic level (so-called “atomic scale heating”). Such a method of heating differs significantly from conventional heating because the kinetic energy of the bombarding ions is transferred to the areas of atomic dimensions and the process is accompanied by extremely rapid cooling ($\sim 10^{14}$ K/s) (Musil, 2006). Kinetic energy E_{bi} has a major influence on the growth of films and their properties. During deposition using ARC or magnetron sputtering, it can be controlled by negative bias applied to substrate U_s , current density on substrate i_s , and deposition rate a_D . Its value is determined according to the following formula (Musil, 2006, 1992):

$$E_{bi} = E_i \gamma_i / \gamma_m = e(U_p - U_s) \gamma_i / \gamma_m e U_s i_s / a_D \quad (4)$$

at a constant substrate temperature T_s , where E_i is the energy of the ions, γ_i is the flow of bombarding ions, γ_m is the flow of sputtered atoms, and U_p is the plasma potential.

During PVD deposition of hard coatings, the kinetic energy E_{bi} , which is defined by the bias U_s , is not the only energy delivered to the growing film. The total energy E_T is the sum of the energies which are determined by other deposition parameters: (a) heating the substrate E_{sh} ; (b) converting the kinetic energy of the bombarding ions E_{bi} and fast neutrals E_{fn} during impact on the surface of the growing film, where $E_p = E_{bi} + E_{fn}$; (c) the heat obtained during the formation of the phases in exothermic chemical reactions E_{ch} ; (d) heating from a sputtered target E_{mt} ; and (e) radiation from plasma E_{rad} . The total E_T energy that is delivered to the growing films can be expressed by the Eq. (5):

$$E_T = E_{sh}(T_s, t_d) + E_p(U_s, i_s, p_T, a_D, t_d) + E_{ch}(t_d + T_{ch}) + E_{mt}(W_d, t_d, d_{S-T}) + E_{rad}(t_d) \quad (5)$$

where T_s is the substrate temperature, t_d is the deposition time, p_T is the total working gas pressure, $W_d = U_d I_d / S$ is the area power density, U_d and I_d are the voltage and current at the cathode, S is the target area, d_{S-T} is the distance target, U_s and i_s are bias and current on substrate and a_D is deposition rate (Musil, 2012).

The combination of the above deposition parameters provides numerous possibilities to influence the structure of the coatings from fibrous and porous through very dense and from columnar to coarse-grained formed by large equiaxial grains.

Mixing Processes

Mixing processes are understood to be the growth of nanocomposite hard coatings by forming ternary, quaternary and multi-element systems. In the deposition of hard coatings, this is accomplished by using compound targets, e.g., CrAl, TiSi, TiB₂ or TaAl, etc. Alternatively, multi-element systems are deposited by co-deposition from compound targets (TiAl target + CrAl target). In this concept, it is not necessary to emphasize substrate bias, such as ion bombardment or substrate heating, although this has some influence on the character of the coating nanostructure. However, in the case of forming nanocomposite structures by mixing processes, chemical bonds, mutual solubility/insolubility of elements, ability of the elements to form solid solutions and inter-metallic phases play more important roles. A very important factor is also the reactive atmosphere e.g., the presence of N₂, O₂, C₂H₂, etc. during deposition, which can significantly affect the growth and structure of hard coatings. The mixing processes can directly influence the formation of the nanocomposite structure in the coatings already during their deposition, that is, the already growing films are formed by the nanocrystalline and/or amorphous phase. The second concept of mixing processes is based on the formation of supersaturated solid solutions which decompose during annealing resulting in nanocomposite coatings.

Low-Energy Ion Bombardment Versus Structure and Mechanical Properties of Hard Coatings

The low-energy ion bombardment of the growing coatings causes atomic “peening” when sputtered atoms that are located on the surface are struck by Ar ions and injected into pores and interstitial spaces in the lattice below the surface of the coatings. The process of incorporation of weakly bonded adsorbed atoms leads to material densification, grain size reduction, and build-up of macrostresses in the coatings (Daniel and Musil, 2013).

Typical hard coatings resistant to wear and erosion are stoichiometric single-phase cubic nitrides of transition metals TiN, CrN, ZrN, TaN, HfN and others prepared by ARC or magnetron sputtering in a reactive atmosphere N₂ and Ar + N₂, respectively. They exhibit a columnar microstructure with elongated grains. Their intrinsic hardness given by the bonds can be influenced by ion bombardment (negative bias) by incorporating point defects into the lattice, increasing density, and reducing grain size. The high density of point and line defects generated during film growth creates obstacles to the movement of dislocations, resulting in strengthening and in an increase in hardness. The values of compression macrostresses are usually in the range of gigapascals (GPa). The hardness of highly stressed TiN deposited at high bias values can reach up to 40 GPa and in the case of CrN up to 35 GPa (LeClair, 1998; Knotek *et al.*, 1991). However, exposure of these hard coatings to temperatures above ~500°C leads to increased diffusivity, annihilation of the defects, atomic rearrangement and recrystallization, causing a reduction in macrostresses and recovery of the structure. As a result, the hardness of the coatings approaches the hardness of bulk TiN (20 GPa) and CrN (14 GPa), respectively. Single-phase hard coatings have found their application particularly in the machining industry. They increase the hardness of the cutting blades and improve the wear resistance of the cutting edges. Due to their lower thermal stability, they are suitable for less demanding cutting processes, turning and milling of carbon steels, some non-ferrous alloys, where the temperature in the tool and workpiece contact does not exceed approximately 500°C. These coatings are also suitable for improving the wear and erosion resistance of forming tools, dies, plastic injection molds and others.

Temperature stability is one of the most important factors for industrial applications. The “tuning” of the above hard coatings by the generation of compression macrostresses by ion bombardment and the loss of hardness at temperatures slightly higher than the deposition temperatures significantly limits their use in high-temperature applications.

Another concept is represented by the superhard TiB_x coatings prepared by nonreactive magnetron sputtering from a stoichiometric TiB₂ target. In this case, Ar low energy ion bombardment affects the chemical composition and character of the nanocomposite structure during growth of the films and the resulting mechanical properties.

Investigated changes of deposition parameters (negative bias U_s expressing kinetic energy E_{bi} according to relation (4) and substrate temperature T_s) (Mayrhofer *et al.*, 2005a; Mikula *et al.*, 2008, 2011), were found to have a significant influence not only on the “design” of the structure and mechanical properties, but also on chemical composition and generation of the internal macrostresses, σ . The TiB_x coatings, in contrast to the TiB₂ target, are overstoichiometric, where the B/Ti concentration ratio decreases monotonically from x = 2.9–2.4 with increasing E_{bi} energy due to the increase in applied negative substrate bias. This can be explained by the different angular distribution of the sputtered B and Ti atoms from the target and by the resputtering of the light boron from the films by Ar ions.

X-ray diffraction analysis (XRD) of TiB_x coatings (Mikula *et al.*, 2011) showed a strong effect of Ar ion bombardment on the structure changes, where the TiB_{2.9} coatings deposited at floating potential (E_{bi} = 8 eV, no applied bias) are characterized by an amorphous or very fine nanocrystalline structure. By applying a bias, the energy of E_{bi} delivered to the growing films was increased > 20 eV supporting the formation of a crystalline hexagonal TiB₂ phase in the coatings. At the same time, a significant preferential orientation of TiB₂ nanocrystallites in the <0001> direction was observed by XRD.

Transmission electron microscopy (TEM) and selected area electron diffraction (SAED) bring a deeper insight into the formation of nanostructures in TiB_x coatings showing that the coatings deposited at very low ion bombardment have randomly oriented nanocrystalline character and the coatings growing at applied negative substrate bias are nanocrystalline and textured (in good agreement with XRD analysis) (Mayrhofer *et al.*, 2005a). In addition, the cross-sectional TEM detail of the textured film revealed a nanocolumnar structure (Fig. 6(a)). Mayrhofer *et al.*, 2005a reported the structure of TiB_x coatings consists of TiB₂ nanocolumns with a diameter of ~20 nm surrounded by an amorphous boron-rich phase (matrix) what is also in good

Fig. 6 (a) Cross-section STEM-DF image of as-deposited $\text{TiB}_{3.1}$ coating with corresponding SAED pattern and the inset showing separated subcolumns by yellow lines. agreement with overstoichiometric character ($\text{B}/\text{Ti} > 2$) of TiB_x coatings (Fig. 6(c)). Such a self-organized nanocomposite structure is also commonly referred to as a two-dimensional (2D) nanostructure.

The effect of low-energy Ar ion bombardment of growing films was also reflected in mechanical properties. TiB_x coatings that grow during low-energy Ar bombardment have a very high hardness > 34 GPa (Fig. 6(b)) (Mikula *et al.*, 2008). The high hardness is mainly related to the intrinsic nature of the material but also to the extrinsic nanocomposite nature of the structure, because the amorphous boron phase enhances the cohesive strength at the grain boundaries. An increase in the kinetic energy of the incident Ar ions affecting the preferential growth of the (0001) crystalline planes parallel to the substrate, resulted in a further increase in hardness up to ~ 50 GPa.

In addition to nanostructure formation, low-energy bombardment of the growing TiB_x coatings by Ar ions due to the incorporation of defects also generated high compressive internal macrostresses (several GPa). Their increase had a positive effect on increasing hardness up to ~ 73 GPa (Mikula *et al.*, 2008). However, increasing the temperature of the substrate caused annihilation of the defects, relaxation of the structure, and a reduction in internal macrostresses accompanied by a decrease in hardness to the value of ~ 34 GPa (Fig. 6(b)). Despite very high hardness, the use of nanocomposite TiB_x coatings is strongly limited by its low oxidation resistance. At temperatures exceeding 500°C , decomposition occurs and the boron from the matrix reacts with the residual atmosphere containing water vapor to form a volatile boric acid. This leads to structural destruction of the coating. In addition, diboride coatings are brittle in nature and are prone to cracking.

Formation of Nanocomposite Hard Coatings by Mixing Processes

Wear and erosion resistant hard nanocomposite coatings can be grown also by adding additional elements, alloying and using a reactive atmosphere during deposition. The most famous representative of the nanocomposite coatings is a ternary Ti-Si-N system developed by the group of Veprék (Veprék *et al.*, 1995a; Veprék and Reiprich, 1995b; Veprék *et al.*, 2000; Veprék *et al.*, 2005). Transmission electron microscopy (TEM) showed that their structure consists of equiaxial cubic TiN nanocrystallites with a typical size of 3–4 nm and SiN_x interfacial layer, (Fig. 7(a)). The thickness of the amorphous SiN_x interfacial layer should be < 1 nm and it

Fig. 7 (a) TEM image of the TiN/SiN_x nanocomposite coating; (b) the oxygen substituting nitrogen in the SiN_x interfacial layer. Reproduced from Veprek, S., 2013. Recent search for new superhard materials: Go nano! Journal of Vacuum Science and Technology A 34, (050822-1–050822-33).

strongly depends on the deposition rate: the higher the speed, the thinner the boundary. The thickness of SiN_x layer determines the hardness: the hardness of ~ 60 GPa was achieved at a thickness of 1 monoatomic layer (it corresponds to ~ 6 at% Si in the coatings). In this case, very strong shear-resistant bonds are formed at the interface between TiN nanocrystallites and SiN_x. When the thickness of the SiN_x layer increased to 2 monoatomic layers (up to 15 at% Si), the cohesive strength decreases, and hardness dropped to about 20 GPa. The nanocomposite structure of Ti-Si-N coatings is temperature stable up to 1000°C.

The most important technological factor determining the nanocomposite structure of Ti-Si-N coatings is the substrate temperature T_s , which must be sufficiently high, at least 550°C and a high deposition rate > 1 nm/s (Veprek, 2013). Under these conditions, decomposition is kinetically controlled by volume diffusion, and the formation of TiN nanocrystallites and amorphous SiN_x interfacial layer occurs faster than Si diffusion into TiN grains. Impurities, especially oxygen, play also very important role in the development of the nanostructure (Fig. 7(b)). Even a very small amount of 0.5–0.8 at% causes a decrease of hardness below 30 GPa, since O₂ atoms incorporated at the interface between TiN nanocrystallites and SiN_x interface layer weaken their bonds. When the amount of oxygen exceeded 0.8 at%, no nanocomposite structure was observed.

Ternary Ti-B-N system represents another very hard nanocomposite coating system. The structure of the TiB_{0.80}N_{0.83} coatings was reported to be composed of 2–3 nanometers cubic TiN and hexagonal TiB₂ nanocrystallites embedded in a disordered, amorphous (Ti) BN_x matrix (Mayrhofer *et al.*, 2006). The hardness of these coatings in the as-deposited state was 37 GPa and increased to 43 GPa after annealing at 800°C due to the densification of the disordered phase. At higher annealing temperatures a coarsening of the nanostructure accompanied by a gradual decrease in hardness to 28 GPa at 1100°C was observed (Veprek *et al.*, 2000). The advantage of Ti-B-N coatings compared to TiB_x is their better thermal stability.

WC/C or W-C:H coatings consisting of tungsten carbide (WC) nanograins embedded in an amorphous (hydrogenated) carbon matrix (a-C:(H)) also represent an interesting concept of nanocomposites formed during growth. They belong to the group of so-called diamond-like carbon (DLC) coatings. W-C:H coatings are usually prepared by ARC or magnetron sputtering from W or WC target in a reactive atmosphere (Ar + acetylene, methane). The addition of hydrogenated carbon from the fragments of the gas precursor resulting from plasma polymerization reactions determines the structural character of the coatings. When the carbon content is 30–40 at%, nanocrystalline W₂C or WC_{1-x} coatings are formed with an a-C content below 7 at% (El Mrabet *et al.*, 2011). They exhibit a high hardness of 35–40 GPa (Abad *et al.*, 2010). An increase in carbon content of up to 65 at% leads to the formation of the nanocomposite WC_{1-x}/a-C coating where the amount of free a-C:H increases to 25 at%. Further addition of carbon to the growing films changes the structure from nanocomposite to fully amorphous and the hardness continues to decrease (El Mrabet *et al.*, 2011; Lofaj *et al.*, 2016; Lofaj *et al.*, 2019a,b,c,d; Makowka *et al.*, 2016; Nouvellon *et al.*, 2017; Voevodin *et al.*, 1999). The character of the structure is also reflected in the tribological properties of the W-C:H coatings. In the case of hard, nanocrystalline WC_{1-x} coatings without a-C:H phase, the self-lubricating ability is low. The coefficient of friction (COF) against a steel ball is above 0.8 and the abrasive wear of the ball dominates. With increasing carbon (and hydrogen) contents and formation of nanocomposite structure, the COF decreases to 0.3–0.6 and adhesive wear becomes the prevalent mechanism. The lowest COFs in the range 0.1–0.2 and the lowest wear rates are achieved in completely amorphous coatings. In this case, the wear mechanisms change from abrasive/adhesive to so-called sliding friction, which is controlled by the formation of a-C:H containing transfer film (Halling, 1983) at the point of contact between the layer and the ball (El Mrabet *et al.*, 2011; Makowka *et al.*, 2016; Nouvellon *et al.*, 2017; Voevodin *et al.*, 1999; Erdemir, 2001; Lofaj *et al.*, 2019a,c). However, the friction versus hardness strongly depends also on the technology of deposition and precursor gas type which affect carbon and hydrogen contents (Lofaj *et al.*, 2019a,b,c,d; Makowka *et al.*, 2016; Nouvellon *et al.*, 2017). The role of hydrogen and its interaction with water vapor in environment has to be

emphasized in this system. It was shown on a-C:H coatings that sufficient hydrogenation can reduce coefficient of friction in dry atmosphere or in high vacuum to <0.01 (superlubricity regime) due to the formation of a transfer layer consisting of hydrogen saturated bonds (Donnet and Grill, 1997; Erdemir, 2000; Erdemir, 2001; Fontaine *et al.*, 2001; Erdemir, 2004; Moura e Silva *et al.*, 2009). Obviously, the case with transfer layer is the exclusion closer to the lubrication mechanisms than to the adhesion, abrasion and deformation mechanisms considered up to now. However, it opens new possibilities to control friction and wear resistance. When returning back to W-C:H coatings, the best combination of hardness, elastic modulus, COF and the lowest wear rates in W-C:H coatings were obtained in the case of HiPPMS and acetylene precursor whereas direct current magnetron sputtering and high target utilization sputtering (HiTUS) with methane produced coatings with slightly lower values (Lofaj *et al.*, 2019a,b,c,d).

W-C:H coatings are successfully used in many engineering applications, e.g., bearings, gearboxes, cutting tools due to high elasticity, chemical inertness and low friction combined with high wear resistance.

Formation of Nanocomposite Hard Coatings by Post-Deposition Annealing

Post-deposition processes, especially annealing, are often used to form nanocomposite structures in hard coatings. This is possible in materials in which, due to the mutual solubility of the input constituents (elements or phases), solid solutions consisting of three or more elements are formed, which usually exist in a wide mutual concentration. Solid solutions are in a thermodynamically unstable state and they decompose into nanocomposite systems due to thermally induced processes often accompanied by a significant increase in hardness.

ARC or magnetron sputtering allow the formation of metastable, supersaturated solid solutions due to the combination of high deposition rates and extremely high cooling rates at the atomic level (10^{14} K/s) (Musil, 2006). This means that during “freezing”, the condensing atoms on the surface of the substrate do not reach the thermodynamically stable state characterized by low formation energy necessary for the formation of a metastable solid solution. For its separation (decomposition) to thermodynamically stable constituents (base phases) a high activation energy is required, and the annealing is one of the ways to supply such energy. The effect can be demonstrated on $\text{Ti}_{1-x}\text{Al}_x\text{N}$ coatings. Under equilibrium conditions, the solubility of AlN in TiN is very low (<2 at% at 1000°C) (Mayrhofer *et al.*, 2014; Schuster and Bauer, 1984) because TiN crystallizes in cubic B1 NaCl lattice, while AlN crystallizes in hexagonal B4 wurtzite lattice. However, during deposition, a supersaturated cubic $\text{Ti}_{1-x}\text{Al}_x\text{N}$ solid solution with an AlN molar fraction up to $x = 0.6\text{--}0.7$ can form (Fella *et al.*, 1988). The temperature stability of this solid solution depends on the proportion of TiN : AlN, but it is sufficiently high. The decomposition occurs at a temperature above 800°C and the resulting structures consisting of nanocrystalline TiN and AlN phases are already thermodynamically stable (Rachbauer *et al.*, 2009; Rachbauer *et al.*, 2011a,b).

The decomposition of the solid solution in a spinodal or precipitation manner changes the mechanical properties of the hard coatings: hardness increases within a certain annealing temperature range and time interval. This phenomenon is called age hardening, and its “size” is determined by the difference in crystal structure and orientation between the decomposing solid solution and the forming new phases.

If the solid solution decomposes in a spinodal manner, rapid demixing of the new phases from the solid solution occurs and a fine-grained nanostructure is formed. The separated phases retain the lattice coherent structure at the early stages of decomposition, e.g., in cubic $\text{Ti}_{1-x}\text{Al}_x\text{N}$, cubic TiN-rich and AlN-rich nanodomains are formed (Mayrhofer *et al.*, 2007, 2003). Their lattice parameters differ slightly from each other (usually up to 5%), causing large microstresses at the interfaces between nanodomains and movement of dislocations is significantly limited. This phenomenon is manifested by resistance to deformation – age hardening. For example, in the case of $\text{Ti}_{0.34}\text{Al}_{0.66}\text{N}$, the onset of decomposition occurs at $\sim 800^\circ\text{C}$ where the hardness increases from ~ 36 GPa to ~ 38.5 GPa (6.5%) (Mayrhofer *et al.*, 2003). Further increase the annealing temperature or time promotes an equilibrium state, i.e., metastable cubic AlN-rich nanodomains are transformed into a stable wurtzite AlN phase incoherent to stable cubic TiN phase. As a result, the microstresses are lost at the interfaces, the structure is relaxed, the movement of the dislocations is not obstructed anymore, and the hardness of the coatings decreases.

A significant hardening effect was also observed in $\text{Ta}_{0.55}\text{Al}_{0.45}\text{N}$ hard coatings, where the hardness increased by 17% from ~ 29.6 GPa to ~ 35.2 GPa during annealing at 1000°C (Mikula *et al.*, 2017). Here, hardening is the result of microstresses at the interfaces between coherent cubic TaN-rich and AlN-rich nanodomains that form during the first stages of spinodal decomposition within the solid solution and prevent further movement of dislocations, see Fig. 8. Subsequent temperature increases to 1200°C led to increased diffusivity, cubic AlN was transformed into stable w-AlN, the structure gradually coarsened, and hardness decreased to ~ 24.6 GPa (Mikula *et al.*, 2017).

Besides the above mentioned ternary systems $\text{Ti}_{0.34}\text{Al}_{0.66}\text{N}$ and $\text{Ta}_{0.55}\text{Al}_{0.45}\text{N}$, hardening associated with solid solution decomposition was reported also in $\text{Cr}_{1-x}\text{Al}_x\text{N}$ (Mayrhofer *et al.*, 2008). In this case, w-AlN precipitates are formed in the cubic CrAlN solid solution (for $x < 0.7$) and c-CrN precipitates in wurtzite CrAlN (for $x > 0.83$), respectively. However, the increase in hardness after annealing at 700°C in $\text{Cr}_{0.32}\text{Al}_{0.68}\text{N}$ was only 2.8% from ~ 30.7 GPa to ~ 31.6 GPa (Willmann *et al.*, 2008).

The thermal stability of the hard coatings defines the temperature, at which the solid solution decomposes, and the formation of nanocomposite structure accompanied by an increase in hardness occurs. Further increase in this temperature and a shift of the beginning of decomposition to obtain coatings for extreme conditions require new approaches. A promising way to achieve higher thermal stability appears to be the formation of quaternary and multi-element systems where hard coatings, in particular $\text{Ti}_{1-x}\text{Al}_x\text{N}$ and $\text{Cr}_{1-x}\text{Al}_x\text{N}$ are alloyed with transition metals from the III-VI group of the Periodic table of the elements (Lind *et al.*, 2011; Forsén *et al.*, 2012, 2013; Rachbauer *et al.*, 2010; Rachbauer *et al.*, 2011b, 2012; Riedl *et al.*, 2013; Chen *et al.*, 2011; Rovere and Mayrhofer, 2008; Rovere *et al.*, 2010). The incorporation of these elements in a substitutional manner replaces Ti and Cr in a

Fig. 8 High resolution TEM image of the $\text{Ta}_{0.55}\text{Al}_{0.45}\text{N}$ coating annealed at 1000°C in vacuum with corresponding Fast Fourier Transformation (FFT) patterns and inverse FFT (IFFT) images for three selected areas A, B, and C. Area A represents region where spinodal decomposition has not yet occurred. FFT pattern shows sharp dots and IFFT image displays lattice fringes without defects. Deformed lattice fringes and several misfit dislocations, which are arranged in low-angle grain boundaries in IFFT of area C shows early stages of spinodal decomposition and formation of coherent nanodomains. Reproduced from Mikula, M., Sangiovanni, D.G., Plašienka, D., *et al.*, 2017. Thermally induced age hardening in tough Ta-Al-N coatings via spinodal decomposition. *Journal of Applied Physics* 121, 155304.

metal sublattices, resulting in a large number of chemical bond variations due to different electron configurations of the individual elements (Mayrhofer *et al.*, 2014).

According to published results describing the quaternary systems $\text{Ti}_{1-x-y}\text{Al}_x\text{TM}_y\text{N}$ (TM = Y, Zr, Hf, Nb and Ta), the AlN concentration interval ($x \sim 0.69$) varies due to the alloying metal when a hard cubic solid solution is formed. While the addition of Y, which is added to improve oxidation resistance, reduces the maximum AlN concentration ($x \sim 0.56$) (Riedl *et al.*, 2013), the alloying by Zr (Chen *et al.*, 2011), Hf (Rachbauer *et al.*, 2012) and Nb (Rachbauer *et al.*, 2011a) does not affect the allowable concentration range of the cubic phase and in case of Ta, the range of x even slightly increases ($x \sim 0.7$) (Rachbauer *et al.*, 2010).

The addition of alloying elements (usually small amounts, $y \leq 0.11$) also affects the phase stability of the cubic solid solution. For instance, the replacement of Ti with pentavalent Nb and Ta increases cohesive energy over a wide AlN concentration range, resulting in the strengthening of bonds between atoms in a cubic solid solution (Mayrhofer *et al.*, 2014).

Strengthening of interatomic bonds is also positively reflected in the thermal stability of quaternary cubic solid solutions. As can be seen in Fig. 9(a)–(c), the alloying of metals from groups III to V slightly decreases the onset temperature of the spinodal decomposition of $\text{Ti}_{1-x-y}\text{Al}_x\text{TM}_y\text{N}$ and the formation of coherent cubic c-AlN-rich and c-Ti (TM)N-rich nanodomains. Unlike $\text{Ti}_{1-x}\text{Al}_x\text{N}$, however, the transformation of c-AlN-rich to w-AlN phase occurs at substantially higher temperatures. Cubic TiTMN phase is stable to high temperatures and, apart from TiYN, does not decompose at temperatures below 1400°C . This is due to the high cohesive forces between atoms, where a much higher temperature is required for phase separation.

Although the structure of $\text{Ti}_{1-x-y}\text{Al}_x\text{TM}_y\text{N}$ solid solutions decomposes spinodally, no significant age hardening during annealing is observed (Fig. 9(d)). An increase of hardness by 2–3 GPa was measured on the Nb and Hf alloyed coatings. In the case of Ta alloying, hardening was not observed, and the addition of Y resulted in a decrease in hardness after annealing.

Another quaternary system is represented by $\text{Ti}_{1-x-y}\text{Al}_x\text{Cr}_y\text{N}$ hard coatings (Forsén *et al.*, 2012) where a metastable cubic TiCrAlN solid solution is formed. The concept of designing these systems is based on a combination of different mechanisms of solid solution decomposition. In the case of $\text{Ti}_{1-x}\text{Al}_x\text{N}$ alloyed by Cr, the temperature stability increases and a small age hardening ($\sim 3\%$) occurs at 1000°C , which is higher than that of $\text{Ti}_{1-x}\text{Al}_x\text{N}$. Indeed, the presence of chromium in forming coherent cubic nanodomains reduces the stresses caused by some lattice mismatch at their interfaces. In addition, Cr suppresses diffusion processes, so that spinodal demixed coherent nanodomains begin to change to stable and coarse-grained phases more slowly and at higher temperatures. As a result, $\text{Ti}_{0.31}\text{Cr}_{0.17}\text{Al}_{0.52}\text{N}$ maintain a high hardness of 35 GPa at temperatures $> 1100^\circ\text{C}$. $\text{Ti}_{0.33}\text{Al}_{0.67}\text{N}$ at the same temperature had considerably coarser-grains and hardness of only 29 GPa.

In the case of CrAlN alloyed by Ti, the decomposition occurs by two different mechanisms. At the grain boundaries of the solid solution, precipitation of the incoherent w-AlN phase occurs simultaneously with the spinodal decomposition and formation of coherent cubic Ti-enriched TiCr(Al)N and Al-enriched (Ti)CrAlN nanodomains. Spinodal decomposition requires less energy than segregation of Al from solid solution towards grain boundaries and subsequent enrichment of the w-AlN boundary phase. Therefore, a higher temperature is required to separate the Al-enriched cubic (Ti)CrAlN phase. This is also reflected in the thermal stability of the mechanical properties where, unlike the unalloyed $\text{Ti}_{1-x}\text{Al}_x\text{N}$, no significant age hardening is observed, but $\text{Ti}_{0.11}\text{Cr}_{0.28}\text{Al}_{0.61}\text{N}$ and $\text{Ti}_{0.31}\text{Cr}_{0.07}\text{Al}_{0.62}\text{N}$ coatings retain high hardness > 32 GPa up to the temperatures above 1000°C . A decrease in hardness occurs when this temperature is exceeded because (Ti)CrAlN decomposes and the proportion of soft w-AlN in the coatings increases.

Fig. 9 Schematic of the structural evolution of metastable $\text{c-Ti}_{1-x}\text{Al}_x\text{N}$ as a function of Ta with corresponding phase fractions (a). The formation of c-AlN- and c-TiN-enriched domains during spinodal decomposition is followed by the precipitation of w-AlN and deteriorating mechanical properties (d) in the final dual phase regime. The evolution of quaternary $\text{c-Ti}_{1-x-y}\text{Al}_x\text{TM}_y\text{N}$ alloys is shown for (b) the formation of dual phase structure (w-AlN + c- $\text{Ti}_{1-z}\text{TM}_z\text{N}$) at high temperatures in the case of group IVB and VB TM elements or (c) the formation of three stable phases after decomposition in the case of Y alloyed $\text{Ti}_{1-x}\text{Al}_x\text{N}$. Reproduced from (d) Rachbauer, R., Stergar, E., Massl, S., Moser, M., Mayrhofer, P.H., 2009. Three-dimensional atom probe investigations of Ti-Al-N thin films. *Scripta Materialia* 61, 725–728. Rachbauer, R., Massl, S., Stergar, E., *et al.*, 2011b. Decomposition pathways in age hardening of Ti-Al-N films. *Journal of Applied Physics* 110, 023515. (c) Mayrhofer, P.H., Rachbauer, F., Holec, D., *et al.*, 2014. Protective transition metal nitride coatings. In: Hashmi M.S.J. (Ed.), *Comprehensive materials processing*, vol. 4. Amsterdam: Elsevier, pp. 355–388.

The investigations of $\text{Cr}_{1-x-y}\text{Al}_x\text{TM}_y\text{N}$ quaternary system alloyed with other transition metals up to now are limited to the studies of the influence of yttrium on oxidation behavior (Rovere and Mayrhofer, 2008; Rovere *et al.*, 2010) and on the influence of Ta on the thermal stability of the Cr-Al-Y-Ta-N multicomponent system (Mikula *et al.*, 2016). The solid solution in an unalloyed $\text{Cr}_{0.49}\text{Al}_{0.50}\text{Y}_{0.01}\text{N}$ began to decompose via precipitation mechanism when the temperature exceeded 900 °C. The structure consisted of stable w-AlN and unstable cubic CrN. A further increase in annealing temperature led to a further decomposition of CrN to Cr_2N accompanied by nitrogen loss and then to cubic Cr. In the case of Ta alloyed coatings, the solid solution decomposed at the temperature exceeding ~1000 °C. The positive effect of Ta on the increase of thermal stability of $\text{Cr}_{1-x-y-z}\text{Al}_x\text{Y}_y\text{Ta}_z\text{N}$ can be explained by strengthening of the interatomic bonds (increase of cohesive energy E_c) when the addition of 11 at% Ta to a solid solution increases its decomposition resistance (E_c increases by 4.5%) (Mikula *et al.*, 2016).

The above mentioned ternary and quaternary hard nitride coatings are already used in industry, especially in machining, due to their significantly higher hardness, temperature stability and oxidation resistance compared to single-phase hard coatings. The control of their wear resistance, despite positive prospects resulting from the hardness increase due to structure manipulation, however, requires additional studies of the control of their elastic properties.

Summary

The analysis of the basic requirements to the mechanical properties of material systems for wear and erosion resistant PVD coatings suggests that a proper combination of hardness, elastic modulus and toughness is required to reduce contributions of the main mechanisms involved in friction and wear processes. The possible ways for the control of these properties, especially hardness, in PVD coatings involve, besides selection of the system with high intrinsic hardness, intentional modifications of the composition and structure via alloying by various transition metals and a wide range of decomposition and precipitation processes, respectively.

Acknowledgments

The funding from the Slovak Research and Development Agency (project No. APVV-17-0320), Science Grant Agency (projects No. VEGA 1/0381/19 and VEGA 2/0017/19) and Operational Program Research and Development (projects ITMS 26210120010 and ITMS: 26220220186) is acknowledged.

This is a reprint of N.S. Jacobson, E.J. Opila, Oxidation and Corrosion of Non-oxide Ceramics, In: Reference Module in Materials Science and Materials Engineering, Elsevier Inc., 2016, doi:10.1016/B978-0-12-803581-8.02350-X.

Introduction

Nonoxide ceramics include carbides, nitrides, and borides. These materials are thermodynamically unstable in air and rely on the formation of a protective oxide for high-temperature stability. The durability of this protective oxide is thus a critical issue in the application of these materials. The requirements for such a protective oxide are (i) slow growing, (ii) self-healing if damaged, and (iii) resistant to corrosive gases and deposits. The emphasis of this chapter is on silicon carbide (SiC) and silicon nitride (Si₃N₄). These ceramics form a protective layer of silica (SiO₂), which meets most of the above requirements. A limited discussion of other ceramics is also included. Detailed reviews of this field are available (Nickel and Gogotsi, 2000; Opila and Jacobson, 2013).

Oxidation studies are concerned with the kinetics of oxide scale formation and the mechanism of reaction. Oxide scale formation may be followed experimentally by oxide thickness or weight change measurements. Application-oriented studies involve scale growth in actual combustion atmospheres or in a mixture of gases that simulate a combustion atmosphere. The microstructure and composition of the resultant oxide scale are examined with electron-optical methods and x-ray diffraction.

Passive Oxidation of Silica-Forming Ceramics

Oxidation rates of silica formers are controlled by the diffusion rate of oxidant molecules through the SiO₂ scale. The pioneering work on pure Si oxidation (Deal and Grove, 1965) is a useful guide to understanding the oxidation of SiC and Si₃N₄. The oxidant reacts with SiC or Si₃N₄ at the SiO₂/ceramic interface and gaseous products (CO or N₂) escape through the scale. The oxidation kinetics are described by a linear-parabolic rate law:

$$x_o^2 + Ax_o = B(t + \tau) \quad [1]$$

Here x_o is the oxide thickness, t is the time, τ is the time correction for any pre-formed oxide, B is the parabolic rate constant and B/A is the linear rate constant. At short times, eqn [1] reduces to $x_o = \frac{B}{A}(t + \tau)$, indicating that the oxide film growth rate is linear with time. At longer times, eqn [1] reduces to $x_o^2 = Bt$, indicating that oxide film growth rate is parabolic with time. Equation [1] describes SiO₂ growth on Si and SiC; SiO₂ growth on Si₃N₄ generally shows parabolic rates, but is more complex and will be discussed in a later section.

At temperatures below 1200 °C in clean environments the silica scale is amorphous, whereas at higher temperatures or in the presence of impurities cristobalite is found. Analogously to Si, the oxidant is molecular oxygen which permeates through the channels in amorphous silica. Crystallization of the silica scale may lower the oxidation rate of SiC somewhat, but only if the scale is completely transformed to cristobalite (Ogbuji, 1997). More detailed information on oxidation of SiC is available in an extensive review (Presser and Nickel, 2008).

Oxidation of Pure Silica-Forming Materials in Oxygen

SiC oxidizes by the following reaction:

The oxidation rate of Si₃N₄ is about the same as SiC at a temperature of 1500 °C. However, the oxidation rate of Si₃N₄ is slower than that of SiC at lower temperatures. This difference may be related to the formation of an inner scale of silicon oxynitride that is found below the silica scale. The overall oxidation reaction can be written in simplified terms as

Evidence suggests the silicon oxynitride is actually a phase of variable stoichiometry, SiO_xN_y (Ogbuji and Jayne, 1993). The oxidation reaction can then be described as a progressive substitution of oxygen for nitrogen.

Oxidation of Pure Silica-Forming Materials in Other Oxidants

Applications of SiC and Si_3N_4 may involve exposure to other oxidants including CO_2 and water vapor. These oxidation reactions are written for SiC as

Similar reactions can be written for Si_3N_4 . Oxidation rates of SiC in CO_2 are negligible relative to those in dry oxygen. However, oxidation rates of SiC and Si_3N_4 in water vapor are enhanced over those observed in dry oxygen since the solubility of water in silica is much higher than that of oxygen. At high water pressures, bubbles are formed in the silica scale owing to the large amount of gases generated in the oxidation reaction. Significant bubble formation results in non-protective scale formation and rapid material consumption. For conditions with flowing gases, water vapor also reacts with the silica scale to form volatile hydroxide species, as discussed below.

Oxidation of Silica-Forming Materials in Impurity-Containing Environments

Low levels of impurities in the environment are incorporated in the silica scale, which increase the number of broken bonds in the silica structure and allow accelerated transport of oxidant to the ceramic, thus increasing the oxidation rate. When Si_3N_4 is oxidized in impurity-containing environments, oxidation rates are effectively the same as those for SiC. A second effect of impurities is a reduced energy needed for nucleation and crystallization of the silica scale, resulting in cristobalite scale formation at temperatures below 1200 °C.

Sintering additives may be added to SiC and Si_3N_4 to aid in the densification process. These additives also effect the oxidation properties of the materials. First, additives such as Al_2O_3 in SiC may become incorporated in the silica scale, thereby reducing the oxidation resistance of the scale (Singhal and Lange, 1975). Rare-earth oxides in Si_3N_4 change the rate-controlling mechanism for oxidation. In these materials, rare-earth cation diffusion outward to the scale surface controls the oxidation rate (Cubiciotti and Lau, 1978) and results in rare-earth silicate formation on the scale surface. These additives also form grain boundary phases, which may oxidize. Grain boundary compositions that undergo volume expansion under oxidation may lead to catastrophic failure and must be avoided (Patel and Thompson, 1988).

In a heat engine, sulfur in the fuel and sodium, either from a marine environment or fuel impurities, may react to form the highly stable species Na_2SO_4 . Condensed-phase Na_2SO_4 deposits lead to hot corrosion. The dew point for Na_2SO_4 deposition can be calculated from thermodynamic considerations and is a function of pressure and the concentrations of sulfur and sodium. The reactive portion of the Na_2SO_4 is Na_2O , released as follows:

The overpressure of SO_3 in the environment sets an activity of Na_2O . If the activity of Na_2O is sufficiently high (basic molten salt), then SiO_2 will be dissolved as follows:

Rapid diffusion through the liquid leads to more rapid oxidation and consumption of the ceramic. This type of corrosion can also occur in basic coal slags (Ferber *et al.*, 1985). Material consumption occurs as surface attack, which can lead to substantial strength degradation.

Volatilization of Silica-Forming Ceramics

One common degradation route for silica-forming ceramics is volatilization by active oxidation. This is formation of $\text{SiO}(\text{g})$ instead of $\text{SiO}_2(\text{s})$. Since $\text{SiO}(\text{g})$ is volatile, substantial material degradation can occur from active oxidation. Active oxidation occurs in flowing gas streams, at high temperatures, and low oxygen partial pressures. In application, this may be a re-entry environment or heat-treating furnace. Active oxidation occurs in regimes defined by the transition oxygen pressures – from active to passive and from passive to active. Note that these are not the same and may differ by orders of magnitude. As oxidant pressure is gradually increased, an active-to-passive transition occurs. The theory for this transition is based on the condition for a stable SiO_2 scale and was developed for silicon by Wagner (1958) and extended to SiC and Si_3N_4 by Singhal (1976). The passive-to-active transition occurs as oxidant pressure is gradually decreased and the SiO_2 scale decomposes. Models for active/passive transitions have been reviewed recently (Jacobson and Myers, 2011).

Another form of volatilization degradation occurs in steam-containing atmospheres, as referred to earlier.

Here the key reaction is

Although a silica scale grows in a steam environment, simultaneous volatilization leads to more rapid material recession (Opila, 1997). These volatilization rates increase with water vapor partial pressure and gas velocity.

Oxidation of Polymer-Derived Silicon-Based Ceramics

An interesting class of recently developed silicon-based ceramics are formed by decomposition of polymer precursors containing Si, C, N, and/or B to carbides or nitrides (Kroke *et al.*, 2000). Initially these materials appeared to have superior oxidation resistance to SiC and Si₃N₄ produced via conventional methods. However, accounting for volatile species formed during oxidation led to rates similar to other SiO₂ forming materials (Nickel, 1999). Nonetheless, these materials offer great flexibility for composition/property tailoring and are a promising new class of ceramics.

Oxidation of Silicon-Based Composites

The discussion thus far has centered on monolithic ceramics. The major issue with these materials is their low fracture toughness. So far the most promising method to improve fracture toughness is with continuous fibers as reinforcements. An example is SiC fibers in a SiC matrix. These types of composites have a unique set of oxidation/corrosion issues. A fiber coating is required so the fiber does not bond to the matrix. The primary fiber coatings are carbon and boron nitride, which are easily oxidized. Models have been developed for the oxidation of the carbon fiber coatings (Filipuzzi and Naslain, 1993). Boron nitride fiber coatings form a condensed phase oxide which interacts with the growing silica film on the fiber and matrix walls (Jacobson *et al.*, 1999).

Refractory Oxide Coatings on Silica-Forming Ceramics: Environmental Barrier Coatings (EBCs)

One attractive method for ameliorating the corrosion susceptibility of ceramic materials is the use of refractory oxide coatings. This approach combines the desirable mechanical properties of a nonoxide ceramic with the chemical stability of a refractory oxide. The primary requirements for such an oxide coating are (1) acts as a substrate oxidation barrier, (2) thermal stability, minimum susceptibility to phase changes, (3) chemical compatibility with substrate, (4) thermal expansion match to non-oxide substrate, and (5) low reactivity with the environment. Finding an oxide which meets all these requirements is challenging. The low reactivity with the environment suggests a low reactivity oxide or reducing the thermochemical activity of SiO₂ in the coating. This limits corrosion reactions [8] and [9]. Mullite (3Al₂O₃ · 2SiO₂) is a good candidate based on its coefficient of thermal expansion (CTE) match to SiC (Lee *et al.*, 1994) (Requirement 4), however the high activity of SiO₂ in mullite leads to only modest resistance to water vapor induced corrosion. A number of other coating compositions have been studied, which appear to limit water vapor enhanced volatility of SiC based ceramics (Lee, 2014). These include barium strontium aluminosilicates (BSAS) and rare earth silicates. The BSAS composition requires a silicon and mullite layer between the outer coating and substrate, which limits the upper operating temperature. Current development focuses on rare earth silicates, such as Yb₂O₃-SiO₂, which may offer improved behavior. Multilayer coatings with inner layers for a bond coat and CTE match and outer layers for durability (Lee, 2014) are promising developments.

Oxidation of Other Nonoxide Ceramics

Alumina (Al₂O₃)-forming ceramics include AlN and Al₄C₃. Al₂O₃ scales are less susceptible to salt corrosion and water vapor-induced volatilization than SiO₂ scales. There is interest in AlN owing to its high thermal conductivity and its slow oxidation rate in dry oxygen. However, it rapidly oxidizes in water vapor-containing environments due to the formation of micropores in the Al₂O₃ scale.

Boria (B₂O₃)-forming ceramics include BN and B₄C. BN is used as a fiber coating for continuous fiber-reinforced ceramic matrix composites. However, B₂O₃ is a liquid above 450 °C and hence a poor protective oxide. Further, it reacts readily with water vapor forming HBO₂(g), H₃BO₃(g), and H₃B₃O₆(g) which are stable under most conditions.

Oxidation of Ultra-High Temperature Ceramics (UHTCs)

Transition metal (typically Zr, Hf, and Ta) borides, carbides, and nitrides are of interest owing to their hardness and high melting points ($T > 3000$ °C) (Wuchina, 2007). Oxidation rates of these materials are rapid for three reasons. (i) Transition metal oxides generally have high oxygen anion diffusivities. (ii) There is generally a large thermal expansion mismatch between the oxide and

corresponding boride, carbide or nitride. This leads to scale cracking and rapid gas transport paths for oxygen to the underlying material. (iii) Porous oxides may form which also have rapid gas transport paths.

Nevertheless, these compounds, or mixtures of them, form the basis for ultra-high temperature composites, which have generated significant interest for thermal protection systems because of the high melting temperatures of both the base material and their oxides.

ZrB₂, a UHTC that has been studied extensively, oxidizes to form ZrO₂ and B₂O₃. The liquid B₂O₃ serves to limit oxygen transport in the porous ZrO₂, but vaporizes at temperatures above 1400 °C (Parthasarathy *et al.*, 2007). SiC additions to ZrB₂ result in the formation of a surface layer of borosilicate glass which extends the surface protection to higher temperatures (Parthasarathy *et al.*, 2012). However, this borosilicate glass layer is also susceptible to vaporization and loss of liquid by shear forces. Recent attempts to improve the oxidation behavior of ZrB₂ have centered on second phase additions such as Cr- or Ta-containing compounds that result in phase-separated glass layers with lower oxygen transport rates (Talmy *et al.*, 2001) or WC additions that improve the density of the ZrO₂ through transient liquid phase (WO₃) sintering (Zhang *et al.*, 2008).

Carbides and nitrides of Zr, Hf, and Ta have also received considerable attention for ultra-high temperature applications. Oxidation of these materials results in the formation of transition metal oxides and gaseous products CO(g) or N₂(g). Gas generation results in the formation of porous oxides. Porous oxides are undesirable under most conditions, allowing rapid oxidant ingress. However, under severe conditions, porous oxides can be favorable, as they allow egress of product gases without rupturing the oxide scale (Metcalf, 2007). Minimization of product gases can be accomplished by utilizing substoichiometric carbides and nitrides such as ZrC_x or HfN_x with $x < 1$ (Wuchina, 2001).

Summary

This discussion has centered on SiC and Si₃N₄, which form slowly growing SiO₂ scales. This oxide is very stable, but susceptible to basic salt corrosion and volatilization under certain conditions. Variants on SiC and Si₃N₄ include polymer-derived Si based composites and ceramic matrix composites. Each material system has a unique set of oxidation and corrosion issues. Refractory oxide coatings offer the possibility of combining the desirable mechanical properties of silicon-based ceramics with the chemical inertness of an oxide. Other non-oxide ceramics generally form less protective scales in oxidizing environments. Nonetheless transition metal compounds have extremely high melting points and combinations of borides, carbides, and/or nitrides may have acceptable oxidation rates for use in short-term ultra-high temperature applications.

Glasses are widely used in modern society in traditional areas of architecture, transport, packaging and tableware but also in advanced technologies such as optoelectronics, microelectronics, communications technologies, energy technologies and bio-medical devices. This section is devoted to Glass and Glass Ceramics and their potential for use in these applications.

The first chapter deals with the Glassy State, defining glass as a non-equilibrium, non-crystalline condensed state of matter that exhibits a glass transition. The chapter expands and elaborates on this definition exploring the fundamental concepts of the non-equilibrium state, non-crystalline structure of glasses which is similar to that of their parent supercooled liquids (SCL). In fact the idea that glass combines features of both liquids and solids is discussed as well as its very unique characteristics. Structural features of glasses are introduced including bridging and non-bridging oxygens and the role of network modifiers. Other important concepts such as relaxation phenomena and glass transition are outlined. The role of critical factors that determine glass formation and crystallization processes, such as glass composition, thermal history, diffusion processes, and viscosity is explored as a crucial basis for further research and development of new materials that readily form glasses and have useful applications.

Following this major introduction to the Glassy State, there follow nine chapters concerned with basic glass types. The first of these reviews the alkali- and alkaline-earth-silica binary glass systems which form the base models for more complex glasses and glass-ceramics. In silica, the basic structural unit is a SiO_4 tetrahedron and all corners are joined to adjacent tetrahedra in a continuous 3-D glass network. When alkali or alkaline-earth cations are mixed with silica, formation of non-bridging oxygens occurs which depolymerizes the network and has a profound effect on the properties of the resulting glass or glass-ceramic. The Mixed Alkali Effect is an important topic for discussion along with phase separation. A broad overview of industrial applications is provided where additives enhance the intrinsic glass properties.

Most of the glasses that people experience in their daily lives, articles such as container glass (bottles), flat glass (windows, etc.) and glassware (drinking glasses), are Soda-Lime-Silica (SLS) glasses which are reviewed in the next chapter along with the raw materials used in current SLS production and forming methods. The relevance of viscosity to glass forming are outlined which has enabled automated processes to be developed around the viscosity-temperature behavior of SLS compositions. SLS glasses can also be produced to suitable optical standard for applications such as windscreens, and they have sufficient mechanical characteristics and chemical durability for use in a wide range of applications.

The introduction of Al_2O_3 into silicate glasses usually imparts greater chemical durability, higher viscosity and glass transition temperatures, improves mechanical properties, reduces devitrification tendencies and lowers thermal expansion. The next chapter reviews Aluminosilicate glasses, which are important for various industrial applications. In practice, almost all silicate glasses incorporate alumina either as an impurity or as a larger chemical constituent. Recent experimental and modeling techniques are reviewed which have substantially improved the understanding of the atomic-scale structure, providing a good basis to better control aluminosilicate glass properties.

The next chapter reviews borosilicates glasses which consist of two kinds of network formers, SiO_2 and B_2O_3 , with network modifiers such as alkali and alkaline earth oxides. This is a very important inorganic glass system used in a broad range of applications such as electronics, lighting, cookware, optics, healthcare, pharmaceutical containers, nuclear waste immobilization, and fiber reinforced composites. These applications originate from the unique properties of borosilicate glasses such as low thermal expansion, high mechanical strength and high chemical durability which derive from the unique glass structure. A feature of borosilicate glasses containing alkali ions is their strong tendency to phase separation, which has been taken advantage of to form low thermal expansion products for cookware or high silica (99 wt%) glass for aerospace applications. This chapter reviews both the basic knowledge and current understanding of structure, topology and properties of borosilicate glasses and introduces developments in property prediction realized by both topological models and MD simulations.

The next chapter describes the fundamental material attributes of chalcogenide glasses (ChGs) and glass-ceramics (GCs) for their use in optical applications. It discusses how ChGs composition (glass chemistry) and morphology (homogeneous or phase-separated glass) can be tailored to produce useful components and how microstructural modification associated with the controlled nucleation and growth of nanocrystals within the parent glass leads to glass ceramics with novel functionalities. Various applications are outlined including components for the mid-wave infrared, such as low-cost lenses via precision glass molding, communication fibers, as well as gradient index optics (imaging), low-loss waveguides (signaling), and nonlinear optics (sensing and lighting).

The next two chapters are concerned with Oxynitride Glasses which are formed by the replacement of oxygen atoms by nitrogen in silicate and aluminosilicate glasses in various M-Si-O-N, M-Si-Al-O-N and M-Si-Mg-O-N systems, where M is a modifying cation such as Mg, Ca, Ba, Sc, Y and the rare earth lanthanides. Representation of four and five-component systems are explained and glass forming regions are outlined. Explanations of structural features such as tri-coordinated nitrogen and the existence of SiO_3N and SiO_2N_2 tetrahedra are given and the roles that Al, Mg and other cations play in the structure of oxynitride glasses are discussed. The second of these chapters provides an overview of the effects of glass composition on properties and crystallization of oxynitride glasses. The effect of nitrogen substitution for oxygen in silicate and aluminosilicate glasses is to increase properties such

as glass transition temperature, elastic modulus, viscosity, hardness and slow crack growth resistance as a result of increased cross-linking within the glass network provided by tri-coordinated nitrogen atoms. Progress in understanding how changes in glass composition affect structural parameters and their relationship to properties is discussed. An overview is given on crystallization of oxynitride glasses outlining nucleation and growth of crystal phases to form glass ceramics with significant increases in elastic modulus over the parent glasses.

The next chapter reviews phosphate glasses which are important materials for a variety of technological applications, in optics as laser glasses, in electrochemistry as new electrode/electrolyte materials, as low temperature sealing glasses, in biomedicine as bioglasses, and as hosts for nuclear wastes. While P_2O_5 is a distorted network glass former oxide consisting of PO_4 tetrahedra interconnected through bridging oxygens, it differs from SiO_2 with its SiO_4 units in that one of the oxygens in PO_4 is double bonded to P and therefore nonbridging. The effects of addition of modifier oxides is outlined and this significantly depolymerizes the phosphate structure with subsequent consequences for properties of these glasses. The chemical and physical properties of phosphates glasses are discussed which are closely related to the modification of the composition and structural network by addition of various metal oxides.

The final chapter in the sequence of glass types reviews Halide glasses. Glass formation is common for single halides (Fluorides, Chlorides, Bromides and Iodides). Those that have been developed for optical fibers are mainly based on fluorozirconates with other components. This chapter reviews the various important glass forming systems, in particular fluoride based glasses which have been more extensively studied and developed, particularly as optical fibers, which extends the range of transmission into the mid infrared range.

The next two chapters are complimentary. The first is concerned with annealing and tempering. Annealing is a basic heat treatment step in the production of all glasses to relieve residual tensile stresses which might render it useless in its chosen application. The relationship between glass viscosity and temperature during manufacture is described and the critical viscosity ranges at which stresses form and at which they can be released are detailed. Tempering is another thermal treatment process, used for instance in car windshields, whereby compressive surface stresses are generated to improve the mechanical properties of a glass and cause safe fracture.

The second of these chapters compares Chemical Strengthening and Thermal Strengthening which are two common methods for improving the mechanical properties of silicate glasses. The generation of surface compressive stresses in glasses are reviewed which are able to mitigate the negative impact of surface flaws through the creation of a residual surface compression layer. The crucial parameters affecting chemical strengthening, particularly the kinetics of ion-exchange of alkali ions, are discussed as well as non-conventional methods for ion-exchange strengthening.

In the next chapter, a general overview of glass properties is given with brief descriptions of chemical durability, mechanical, thermal, electrical and optical properties of glass and the effects of glass composition on properties. This is followed by a more in-depth review of optical glass, describing the historical developments and how scientists working with optical instruments identified the need for novel glass types with essentially different dispersion properties. The starting point was the basic electro-dynamics of light and its interaction with matter. At the same time, relevant glass types were under development and thus modern optical glass chemistry was born. The chapter reviews the interplay of the progress of optical design, the arising needs for novel optical materials and the corresponding invention of special optical glasses.

The next two contributions are concerned with glass fibers. In the first of these the focus is on silicate-based glasses because of their great commercial importance as reinforcement fibers for polymer matrix composites. There is also reference to the use of glass fibers in the biomaterials sector as scaffolds in tissue engineering. This is followed by a chapter which examines how the properties of silica (SiO_2) glass make it the medium of choice for optical fiber communications. Topics covered range from the viscosity of silica over its working temperature range that make it suitable for drawing into fiber, to its suitability as a substrate material for trace dopants in modifying its refractive index, to it being the only material that, when doped with the rare earth element erbium, provides optical gain in the same portion of the electromagnetic spectrum as its optimal region of transparency.

The next two chapters cover sol-gel methods for preparing glasses, the first being an introduction to the topic. The second presents a review of the advances in the sol-gel route for preparation of glasses and glass-ceramics, taking into account the physical and chemical aspects governing the process. An overview of the most important developments and applications including sol-gel coatings for optical, as well as protective or photocatalytic, applications. Biomaterials prepared by sol-gel are also highlighted.

The next chapter reviews the field of glass-ceramics (GC). The glass-ceramic process is described involving melting to form a glass followed by a two-stage heat treatment to form crystalline phases by controlled nucleation and crystallization. The advantages over the conventional ceramic forming process are discussed. This is followed by outlines of the major applications of glass-ceramic systems because of their specific combinations of mechanical and functional properties. Applications include: lamp bulb seals, because of GC higher mechanical properties, better temperature resistance, and tailored thermal expansion; hermetic gas sealants for SOFC batteries that must withstand the working temperatures over long times; joining of SiC-based materials, for example in nuclear reactors where GCs provide irradiation stability, chemical inertness, toughness, and high temperature performance; bioactive glass-ceramics, which are easy to synthesize and their mechanical properties are higher than those of glasses; dental restorations; GC insulators, dielectrics for high power capacitors; pyroelectric, piezoelectric and thermoelectric GCs; solid state electrolytes for rechargeable batteries; machinable GCs: GCs for radioactive and hazardous waste encapsulation.

The next contribution is on glass reactive sintering which refers to several technologies, with the common trend of viscous flow sintering of glass combined with physical and chemical reactions. It reviews the distinctive characteristics of glass sintering with reactions having a significant impact on the chemical composition and phase assemblage of the resulting products. The more

conventional technology of sinter-crystallization (sintering with concurrent devitrification of glass powders) is presented in its more recent developments (e.g., additive manufacturing); a survey of more recent technologies concerning extensive glass/oxide additive interaction is also presented. The wide range of combinations of glass powders, oxide additives, reactive binders, etc. opens the way for a new generation of glass-based products in key areas related to health, energy, and environment that are crucial for future well-being.

The use of glasses as hermetic seals is the topic of the next chapter. The joining of glass/metal or glass/ceramic interfaces is a field of research which covers energy-generation systems, electricity, microelectronics and protection against corrosion. An overview is given of the interdisciplinary approach to research and development connecting different areas of knowledge such as the design of glass sealing compositions, melting and processing, adherence and inter-diffusion processes and also the most modern techniques for the study of surfaces and interfacial reactions. Relevant compositions are presented along with the steps of the sealing process as well as conventional and new applications for glass and glass-ceramics as sealing materials.

The final chapter in this section reviews Glasses and Glass-ceramics for Nuclear Waste Immobilization. Oxide glasses – and mainly borosilicates – are the only host used to incorporate high level radioactive waste. Their structural flexibility allows them to accommodate almost all the elements present in waste resulting from spent nuclear fuel reprocessing, and their good self-irradiation resistance and chemical durability associated with their ease of fabrication by melting and casting explain the success of glassy wasteforms today. Descriptions are given of vitrification, and how glass formulation has been adapted to the changes in waste composition. The developments in the precise knowledge of the structure and properties of nuclear glasses are outlined and in particular the way the various elements present in the waste are incorporated into the glassy network and how this can be optimized by modifying the composition of the glass. The long-term behavior is reviewed of nuclear glasses during their geological storage, such as in submerged aqueous media, as well as the impact of internal irradiation on glass structure and properties. While the presence of crystals in nuclear glasses was regarded as undesirable new developments are described to accept partial crystallization for some waste if the containment of the final wasteform remains acceptable, leading to glass composite materials (GCM). Belonging to this family of wasteforms, glass-ceramics that can be obtained by controlled crystallization of glass bearing radio-nuclides are speculated for instance as materials to immobilize actinide-rich waste.

Glasses are important materials that are crucial to human civilization and this section has covered a broad range of subjects related to the most important glass types and other areas of glass science and technology.

The Glassy State

Maziar Montazerian and Edgar D Zanotto, Federal University of São Carlos, São Carlos, SP, Brazil

© 2021 Elsevier Inc. All rights reserved.

Introduction

Glasses have been, beyond any doubt, vital materials for the development and well-being of human civilization and are now ubiquitous in our everyday lives. Natural glasses, such as obsidian, are nearly as old as the universe, whereas novel useful glasses are being discovered daily (Zanotto and Mauro, 2017; David Pye, 2016). As summarized in *Welcome to the Glass Age*, by Morse and Evenson (2016), *Glass: the eye of science* by Bolt (2017), and *Glass and Glass-Ceramic Technologies to Transform the World* by Hench (2011), many outstanding innovations can be cited, where glass was the critical material, for instance, optical glass fiber networks that span the globe (Ballato *et al.*, 2017), thin and strong glass sheets for television sets and cell phones (Varshneya and Bihuniak, 2017), high-strength and exceptionally elastic metallic glasses (Li *et al.*, 2019; Shi, 2019), semiconductive chalcogenide glasses (Lin *et al.*, 2018), bioactive glasses for healthcare (Montazerian *et al.*; Montazerian and Zanotto, 2017), and many other incredible applications described in other chapters.

A diverse variety of glass-forming chemistries exist, having a wide range of structural building blocks from which a glassy material is constructed. The detailed nature of these chemical building blocks and how they are connected depend on the particular nature of the chemical bonding in these systems. Here we defend the concept that glass itself is a fascinating state of matter combining aspects of the liquid and solid states. Before elucidating the idea of the glassy state, some basic concepts are defined which will render the modern definition of the glassy state more tangible.

Basic Definitions

Solid

A solid is one of the three traditional, basic states of matter (the others are liquid and gas) where the atomic structure and chemical forces are strong enough to keep that atomic structure and external shape cohesive even when it is not confined in a receptacle. Solids exhibit certain characteristics that distinguish them from liquids and gases. All solids have, for example, the ability to resist some level of forces applied either perpendicular or parallel to their surface, i.e., normal or shear loads, respectively. Such properties depend on the nature of the atoms that form the solid, the way these atoms are arranged and the bonding characteristic between them (see “Relevant Websites section”).

Liquid

Liquid is another principal condensed state of matter; intermediate between a gas and crystalline solid. A liquid will retain its volume, but not its shape when it is poured from one vessel to another. The shape variation might occur in a short or very long time; liquids flow under the force of gravity (or even smaller forces) until their shape conforms to that of the container that they occupy (see “Relevant Websites section”).

Viscous Flow Versus Creep

A characteristic feature of liquids, viscous flow is a cooperative movement of several atomic groups under a positive force field, e.g., gravity. This is quite different from diffusive deformation of solids under stress, such as creeping. While both types of deformation are characterized by rates proportional to the applied stress, they are very distinct on the molecular scale (Hopper and Uhlmann, 1974). The mechanism of creep depends on temperature and applied stress. Dislocation glide or diffusional-flow mechanisms typically dominate creep deformation, and their kinetics is completely distinct from the viscous flow. The most celebrated creep mechanisms are bulk diffusion (Nabarro–Herring creep), grain boundary diffusion (Coble creep), thermally activated and climb-assisted dislocation glide – where the climb is an enabling mechanism, allowing dislocations to move around obstacles. Most of these mechanisms are controlled by vacancy (in single crystals) or grain boundary diffusion (in polycrystals) and are generally triggered after a minimum threshold stress is surpassed, which is composition and temperature dependent. For a detailed description, the reader is invited to study (see “Relevant Websites section”; Poirier, 1985).

Supercooled Liquid (SCL)

SCL is the liquid state that exists between the melting point or liquidus temperature and the glass transition temperature. Supercooled liquids are thermodynamically metastable and tend to crystallize (Zanotto and Mauro, 2017).

Crystal

A crystal is a solid material having a well-ordered atomic structure on a periodic lattice. Crystals can be thermodynamically stable or metastable (they can transform into other crystalline structures under pressure or temperature). Crystalline materials may be composed of a single crystal, or they may be polycrystalline (Zanotto and Mauro, 2017). They can be permanently deformed under an external threshold stress.

Non-Equilibrium Thermodynamic State

The thermodynamic state of a material can be either an equilibrium state or a non-equilibrium state. The values of thermodynamic properties define a thermodynamic equilibrium state. A non-equilibrium state is much more difficult to explain and generally requires the existence of a condition called local thermodynamic equilibrium, which exists when thermodynamic equilibrium occurs locally within a series of small volumes that make up the system. Conversely, a thermodynamic property is any characteristic of a system whose numerical value depends only on the (local) thermodynamic equilibrium state of the system and is independent of how that state was attained (Robert, 2011).

Ergodic State

Ergodicity denotes a system where the time and ensemble averages of properties are equivalent. This implies that the ergodic system explores a sufficient fraction of its configurational phase space to reach this equivalence (Mauro *et al.*, 2010, 2007).

Relaxation

Non-equilibrium materials tend to relax toward the equilibrium condition, even in the absence of any external stress field. Their properties are liable to reach the values of the equilibrium state. This change from a non-equilibrium to an equilibrium state is thus called relaxation (Robert, 2011).

Non-Crystalline Material

A material which lacks the long-range atomic and molecular periodic order of a crystal is called non-crystalline. As first pointed out in the pioneering work of Zachariasen (Zachariasen, 1932) in 1932, the non-crystalline network of oxide glasses is not periodic and symmetrical as in crystals. However, it is not entirely random because the internuclear distances do not fall below a given minimum value.

Amorphous

An amorphous material (AM) has a non-crystalline structure that differs from that of its isochemical liquid, and does not undergo structural relaxation and the glass transition when heated. Please note the distinction between glasses and amorphous solids; the reader is referred to Gupta (1996) for further details. Both glasses and amorphous solids are examples of non-crystalline materials, but glasses exhibit a glass transition, whereas amorphous solids do not. We will show later that glasses relax to the SCL state then crystallize, whereas amorphous materials crystallize without undergoing any relaxation process. Moreover, AM cannot be made from quenching a liquid; amorphous materials are made, e.g., by evaporation-condensation onto a cold substrate or by the destruction of crystalline structures by high energy.

Crystallization

Glasses are unstable against the SCL state. All non-crystalline substances (glasses, SCL or AM) are metastable against their crystalline (solid) counterparts. Hence, they tend to reach thermodynamic equilibrium via crystal nucleation and growth. Crystallization is thus the ultimate fate of all non-crystalline materials (Zanotto and Mauro, 2017).

The Glassy State

A recent definition of glass reads (Zanotto and Mauro, 2017): “Glass is a non-equilibrium, non-crystalline state of matter that appears solid on a short time scale but continuously relaxes towards the liquid state.” This is an intuitive description for the general public. A more detailed definition is “Glass is a non-equilibrium, non-crystalline condensed state of matter that exhibits a glass transition. The structure of glasses is similar to that of their parent supercooled liquids (SCL), and they spontaneously relax toward the SCL state. Their ultimate fate, in the limit of infinite time, is to crystallize.” This definition can also be applied to “non-standard” types of glasses, such as liquid crystals, which are partially crystalline but have a vitreous matrix that exhibits a glass transition (Zanotto and Mauro, 2017).

Fig. 1 Schematics of how a first-order thermodynamic property, such as volume or enthalpy, varies with temperature for a glass-forming liquid. Four distinct states are shown: liquid, supercooled liquid, glass, and crystal. T_m = melting point or liquidus temperature, T_g = glass transition temperature. Glass 1: changed from the SCL at a lower cooling rate, and hence, at a lower glass transition temperature (T_{g1}) than glass 2; which became frozen at a higher glass transition temperature (T_{g2}). Most glasses first relax to a SCL state (gray arrow), and then the SCL eventually crystallizes at any temperature below T_m (green arrows). Adapted from: <https://www.youtube.com/watch?v=eYlWiFeKt5o&t=16s>. The glass transition unveiled – A theatrical version.

In this chapter, we dwell on the key concepts of the above definition to dig deeper into the glassy state of matter. To understand its key features, we review here the most well-known diagram in glass science (**Fig. 1**). This figure shows how a first-order thermodynamic property such as molar volume, entropy, or enthalpy varies with temperature for a glass-forming liquid. Through this plot, glass formation is discussed, and the relevant concepts are explained. The different regions in this figure are described as follows (**Zanotto and Mauro, 2017**):

- (1) In equilibrium, the thermodynamically stable liquids only exist above the melting point (T_m) or *liquidus* temperature (T_L). For any given composition, the *liquidus* temperature is the highest temperature of thermodynamic equilibrium between the solid and liquid phases, above which any crystal is unstable and will dissolve in the liquid phase. T_L equals T_m for congruently melting compounds. Therefore, when the temperature is above the T_m of a pure system or T_L for a multi-component system, the liquid is in thermodynamic equilibrium and never crystallizes.
- (2) Supercooled liquids exist between T_m and the glass transition temperature, T_g . They are metastable, i.e., a thermodynamic barrier must be overcome for crystal nucleation to take place, but they eventually crystallize (green arrows) after a certain time.
- (3) If an equilibrium liquid is cooled quickly enough to avoid crystallization, a SCL is obtained. The structure of the liquid rearranges quickly to attain this metastable equilibrium state as the temperature decreases. However, upon continued cooling, as the temperature decreases, the relaxation time of the SCL increases and the system is eventually (temporarily) frozen when the relaxation time exceeds the laboratory observation time. When this happens, the atoms do not have sufficient time to rearrange to the metastable equilibrium state, i.e., the structural reorganization is kinetically arrested. As a result, the enthalpy deviates from the SCL line and follows that of the configurationally frozen system. This freezing of the system occurs continuously and results in a non-equilibrium material known as “glass.” Since the glass transition is a kinetic freezing process, the final enthalpy of glass depends on the cooling rate, which is related to observation time. When the cooling rate is high, the system has less time to relax into a lower energy structure, which leads to greater enthalpy in the final glass. This phenomenon is expressed in **Fig. 1**. This figure shows that glass 2 (e.g., fiberglass) has higher enthalpy or volume than glass 1 (e.g., a monolithic piece of glass having the same composition as the fiber), since the former is cooled faster than the latter. The temperature range between the equilibrium SCL and the frozen liquid (glass) is defined as the “glass transition” range. The temperature at the intercept between the two lines extrapolated from glassy and liquid enthalpies is the characteristic value of the T_g . Due to its higher cooling rate, glass 2 has a higher T_g (T_{g2}), whereas glass 1 has a lower T_g (T_{g1}).

Is Glass a Solid or Liquid?

For many decades, researchers have attempted to define glass as either a liquid or, more typically, as a solid. However, this binary thinking does not do justice to the true complexity of the glassy state, which combines features of both liquids and solids, and also brings along its unique characteristics. Glass appears to be solid on a typical observation time scale: it has mechanical rigidity and elasticity, it can be scratched and fractured, ring and resonate, just as a solid. However, the structures of all glasses are very similar to those of their corresponding SCL, i.e., a liquid property. It should also be noted that glasses also have a property that is unique to the glassy state due to their non-equilibrium and frozen nature; they undergo spontaneous relaxation towards the SCL state. Additionally, unlike regular solids and liquids, the properties of a glass depend not only on its composition and the current temperature and pressure but also on its entire thermal and pressure histories (**Zanotto and Mauro, 2017**). Moreover, it has been

shown that the glassy state itself cannot be expressed as any linear combination of supercooled liquid states (Mauro *et al.*, 2009b; Mauro and Loucks, 2009). The glassy state is, therefore, unique and can be classified as its own (non-equilibrium) state of matter.

The existence of any glass is transient and temporary since it will continuously relax toward the supercooled liquid state and ultimately crystallize (solidify). Given this combination of solid-like and liquid-like properties, glass could be considered as a special hybrid state of matter (the glassy state), where the solid-like properties are evident when probing its mechanical response on a short timescale, but their non-crystalline structures, spontaneous relaxation to the SCL followed by viscous flow, and crystallization behaviors make them more akin to non-equilibrium “frozen” liquids (Zanotto and Mauro, 2017).

Besides the above discussion on the *solid*, *liquid*, and the *non-equilibrium* nature of glass, there are some key features in the definition of glass that should be elaborated upon. These characteristics include relaxation, glass transition, glass structure, and crystallization.

Relaxation

From relatively low to intermediate viscosities ($10^0 < \eta < 10^{11}$ Pa s), most glass-forming melts usually behave as Newtonian liquids, and immediately relax to relieve any applied stress. However, at extremely high viscosities ($\eta > 10^{13}$ Pa s), when the structural relaxation times become longer than the experimental times, these liquids respond to the “rapid” application of a stress as if they were actually elastic materials. It follows that there must be an intermediate range of viscosities where the response of these melts to the application of a stress is intermediate between the behavior of a liquid and that of an elastic solid. Since this behavior has aspects of both viscous and elastic responses, it is known as viscoelasticity or viscoelastic behavior (Shelby, 2005).

The most common basic model for viscoelasticity, known as the Maxwell model, reads (Shelby, 2005):

$$\sigma_t = \sigma_0 \exp\left(-\frac{G(T)}{\eta(T)}\right) \quad (1)$$

where σ_t is the stress at time, t , σ_0 is the stress at time zero, $G(T)$ is the shear modulus, and $\eta(T)$ is the viscosity. The ratio $\eta(T)/G(T)$ has the dimensions of time and is equal to the time required for the stress to decay to $1/e$, or 0.367, of its initial value. This time, which is commonly represented by τ_R , is known as the *average relaxation time*. The stress relaxation time, τ_R , is thus expressed in terms of viscosity and G_∞ ,

$$\tau_R(T) = \frac{\eta(T)}{G_\infty} \quad (2)$$

where G_∞ is the shear modulus measured at infinitely high frequency, which changes little with temperature, whereas both $\tau_R(T)$ and $\eta(T)$ vary dramatically with temperature. The viscosity and stress relaxation time are roughly proportional since the temperature dependence of G_∞ is small. Building on the above definition and considering a typical shear modulus for oxide glasses (in Maxwell’s equation), Angell proposed an operational definition of T_g as the temperature at which the viscosity of the supercooled liquid is equal to 10^{12} Pa s (Angell, 1991).

Replacing $\eta(T)/G(T)$ by τ_R , the expression can be written as:

$$\sigma_t = \sigma_0 \exp\left(-\frac{t}{\tau_R}\right) \quad (3)$$

which describes an exponential relaxation curve. If τ_R is very small, relaxation will occur so rapidly that normal measurements may indicate that the process is instantaneous. If τ_R is very long (e.g., at room temperature for a window glass), the relaxation rate may be so slow that no relaxation is detected in routine measurements. It is reasonably assumed that the infinite frequency shear modulus is essentially temperature independent, the temperature dependence of τ_R can be attributed to the temperature dependence of the viscosity. Assuming a typical room temperature value of G_∞ of $\sim 3 \times 10^{10}$ N m⁻² for oxide glasses, the value of τ_R at a viscosity of 10^{12} Pa s is 33 s, meaning that significant relaxation occurs after ~ 33 s. It follows that relaxation at temperatures in the glass transition range would be expected to occur over times ranging from hours to seconds, as the viscosity decreases with increasing temperature. Since most experimental measurements of T_g involve heating specimens at rates of 3–20 K min⁻¹, we expect that these measurements will indicate relaxation processes occurring on similar timescales ($\sim 1/10$ min = 6 s) and that the T_g values refer to viscosities of the order of 10^{11} to 10^{12} Pa s. This relaxation concept is instrumental in understanding the glass transition phenomenon.

The structural relaxation process can be best appreciated in isothermal experiments, for instance by following refractive index changes of a glass with time at several temperatures below the original T_g as shown schematically in Fig. 2. Such a process has been frequently formulated by the most traditional relaxation equation, often called the KWW (Kohlrausch–William–Watts) function, as follow (Hodge, 1994):

$$\varphi(t, T) = \frac{p(t) - p_\infty(T)}{p_0(T_f) - p_\infty(T)} = \exp\left[-\left(\frac{t}{\tau_k(T)}\right)^{\beta(T)}\right] \quad (4)$$

where φ is the relaxation parameter, p is a property that varies during relaxation (for instance, density, specific heat, or refractive index), p_∞ is the property value for a treatment time long enough for full relaxation, p_0 is the initial value of that property, β is a dimensionless factor, $0 < \beta \leq 1$, and τ_k is the characteristic relaxation time, which can be calculated by the following equation:

Fig. 2 Time dependence of the refractive index for lead metasilicate glass. Relaxation experiments were performed at 25K below the original glass transition temperature, where the sample was previously treated to equilibrate ($T_g - 25 = 651\text{K}$). The full line is the regression with the KWW equation. The horizontal dotted line shows the refractive index at the initial time. Reproduced from Lancelotti, R.F., Cassar, D.R., Peittl, O., Zanolto, E.D., 2019. Refractive Index Investigation of Structural Relaxation of Oxide Glasses, (in preparation).

$$\tau_k(T) = \frac{\beta(T)\tau_R(T)}{\Gamma\left(\frac{1}{\beta(T)}\right)} \quad (5)$$

where Γ is the gamma function, and τ_R is the average relaxation time, which can be calculated by the Maxwell equation, Eq. (2), using the values of η and G_∞ (10–50 GPa for silicate glasses).

From relaxation experiments, such as that shown in Fig. 2, one can fit Eq. (4) to calculate the values of β and τ_k for a given glass at different temperatures. The KWW equation usually fits quite well the experimental relaxation kinetics carried out not far below the original T_g (say, down to $T_g - 30\text{K}$). However, it does not have any predictive power for the variation of relaxation time with temperature, $\tau(T)$, because β also varies with temperature. The value of β itself is relevant because it gives a measure of the width of the distribution of relaxation times of the numerous “cooperatively rearranging regions” (CRR) that exist in glass formers (Hodge, 1994). The lower the value of β , the wider the relaxation time distribution.

More elaborate empirical models exist, such as the TNM model (Tool–Narayanaswamy–Moynihan) (Hodge, 1994), and the modified recent MAP model (Mauro–Allan–Potuzak) (Mauro *et al.*, 2009a; Guo *et al.*, 2018; Mauro and Mauro, 2018; Wilkinson *et al.*, 2018). The MAP can be used to describe glass relaxation. More details about the implementation of the KWW and MAP equations are provided in Guo *et al.* (2018) and Mauro and Mauro (2018). Moreover, recently a Python-based code was designed by Wilkinson *et al.* to retrieve the evolution of the fictive temperature, viscosity, and relaxation time using the inputs from the temperature path and set of material properties, including the viscosity parameters (Wilkinson *et al.*, 2018).

Fig. 2 shows the structural relaxation kinetics at 25K below the fictive temperature temperatures for lead metasilicate glass (Lancelotti *et al.*, 2019). The refractive index measurements proved to be a very good technique to follow the relaxation during isothermal treatments because the uncertainty of the measurements was only in the fifth decimal place. The KWW equation fitted the experimental data quite well; the full line is a regression obtained using the model. The dotted line represents the initial value of the refractive index for all temperatures. The fitted parameter of the KWW equation, as well as the average relaxation time, calculated by Eq. (2), are shown in Table 1 (Lancelotti *et al.*, 2019).

Glass Transition

Glasses only exist below their respective glass transition temperature, T_g . They are thermodynamically unstable and spontaneously relax toward the supercooled liquid state at any nonzero temperature (gray arrow in Fig. 1). The glass transition takes place at T_g , the temperature where the experimental or observation time, t_{obs} , is similar to the average structural relaxation time of the SCL, τ_R . On the heating path, a glass changes to a SCL at T_g , whereas on the cooling path the SCL temporarily freezes into the glassy state. In isothermal experiments, at any positive temperature, above or below T_g , for sufficiently long times ($t_{\text{obs}} \gg \tau_R$), any SCL or glass relaxes, and then eventually crystallizes to a solid with well-organized atomic structures at short, medium and long range, which is thermodynamically stable below T_m (arrows in Fig. 1; Zanolto and Mauro, 2017).

T_g depends on the cooling rate (observation time). There is a standard value called the standard calorimetric glass transition temperature (T_g), which is measured using a differential scanning calorimetry (DSC) at a heating rate of 10 K min^{-1} . For oxide glasses, this T_g typically corresponds to a viscosity of *ca.* 10^{12} Pa s . Furthermore, T_g varies with composition, thermal history, and mechanical history. Whereas the crystallization of liquid results in an abrupt discontinuity in thermodynamic variables (e.g., volume and enthalpy), the glass transition is not a thermodynamic phase transition. A thermodynamic consequence of this kinetic

Fig. 3 Temperature dependences of the isobaric heat capacity (C_p) for calcium metaphosphate glass (CaP_2O_6), which were determined using DSC during the heating-cooling cycle (rate: 10 K min^{-1}). The glass-liquid transition during upscan is featured by the C_p jump, $\Delta C_p(T_g)$, whereas the liquid-glass transition is reflected by the C_p drop. The onset temperature of the glass-liquid transition, i.e., the intercept between the extrapolated glass C_p line and the line with the maximum tangent of the C_p rising curve, is defined as the standard glass transition temperature T_g . Reproduced with permission from Yue, Y., 2008. Characteristic temperatures of enthalpy relaxation in glass. *Journal of Non-Crystalline Solids* 354 (12–13), 1112–1118.

transition is that configurational degrees of freedom in the glass are (temporarily) frozen, leading to a sharp loss of second-order thermodynamic properties, such as heat capacity and thermal expansion coefficient (Guo *et al.*, 2018).

This event and key parameters of the calorimetric glass transition are illustrated in Fig. 3, where the changes of the isobaric heat capacity (C_p) with temperature are recorded for a calcium metaphosphate glass during the DSC upscan (heating) and its corresponding liquid during the subsequent downscan (cooling) at the standard rate of 10 K min^{-1} (Zheng *et al.*, 2019; Yue, 2008). The glass transition occurs over a range of temperatures (ΔT_g in Fig. 3), but it is convenient to define a single temperature as an indication of the onset of the glass transition range for a glass. This temperature is termed the standard glass transition temperature (T_g) (Zheng *et al.*, 2019). The standard T_g value is determined as the crossing point temperature of the extrapolated C_{pg} line and the extrapolated line of the rapidly rising C_p line. This T_g value is equal to the temperature ($T_{g, \text{infl}}$) corresponding to the inflection point of the C_p drop line during cooling (see the blue filled circle in Fig. 3). As such, the glass-to-liquid transition during heating is manifested by $\Delta C_p(T_g)$, i.e., the C_p jump from glass C_p at T_g (denoted C_{pg}) to liquid C_p at the ending temperature of glass-to-liquid transition ($T_{g, \text{end}}$) (denoted C_{pl}) (Yue, 2008; Guo *et al.*, 2011). The T_g of different glass systems can vary from below 50K to above 1500K (Zheng *et al.*, 2019).

Ergodicity

The glass transition is intimately connected to the notion of ergodicity. For an ergodic system, the time and ensemble averages of properties are equivalent and implies that the system explores a sufficient fraction of its configurational phase space to reach this equivalence (Mauro *et al.*, 2010, 2007). However, a system that is initially ergodic can become non-ergodic, i.e., if sufficient configurational degrees of freedom are lost. This breakdown of ergodicity can occur either discontinuously or continuously, depending upon the details of the system. Whether or not a system is ergodic is a question of timescale. There are two relevant time scales involved when an experiment is taking place. One is the internal time scale (τ_{int}) on which the dynamics of the system occur, which is essentially a relaxation time over which a system loses “memory” of its preceding states. This internal time scale is related to τ_R . The other is the external time scale (τ_{ext}) on which properties are measured, which defines a measurement window over which the system is observed. The Deborah number (Reiner, 1964) of an experiment is defined as the ratio of internal to external time scales,

$$D = \frac{\tau_{\text{int}}}{\tau_{\text{ext}}} \quad (6)$$

A large Deborah number ($D \gg 1$, $\tau_{int} \gg \tau_{ext}$) indicates that the system visits only a small subset of the available points in phase space during the external (i.e., observation) time scale. Hence, a system with a large Deborah number is non-ergodic. On the contrary, a very small Deborah number ($D \ll 1$, $\tau_{int} \ll \tau_{ext}$) means that the system can explore a greater portion of phase space during the observation time, which leads to an ergodic system. Therefore, both the internal relaxation time of a system and the external observation time determine the ergodicity of the system.

Palmer (1982) introduced the notion of “broken ergodicity,” in which glass can be described as an ensemble of components of the phase space, where each component exhibits internal ergodicity, but transitions between components are not allowed. This breakdown of ergodicity occurs when the Deborah number of the system is near unity, $D \approx 1$. This breakdown is the most fundamental definition of the glass transition, i.e., where the internal relaxation time of a glass-forming system is equal to an external observation time scale ($t_{obs} = \tau_{int}$). The transition between ergodic and nonergodic states, where $D \approx 1$, corresponds to the glass transition. For any realistic system, the loss of ergodicity is a gradual process, i.e., the glass transition involves a continuous breakdown of ergodicity. Thus, the glass transition is fundamentally a process in which a supercooled, ergodic liquid is gradually frozen into a non-equilibrium, non-ergodic glassy state. The glassy state can be observed only when the relaxation time scale of the system becomes much longer than the observation time scale, i.e., the glass transition only takes place when a finite observation time is defined (Varshneya and Mauro, 2019).

In summary, given the above definition, T_g refers to a temperature where the time of observation (of an experiment), t_{obs} , is of the same order as the average structural relaxation time, τ_R , of the supercooled liquid; $t_{obs} \sim \tau_R$. According to Maxwell's relation, $\tau_R = \eta/G_\infty$. For typical oxide glasses in classical laboratory experiments by, e.g., DSC or dilatometer, carried out at $5\text{--}20\text{ K min}^{-1}$, $\eta(T_g) \sim 10^{12}\text{ Pa s}$ and $G_\infty \sim 3 \times 10^{10}\text{ Pa}$, hence, $\tau_R \sim 33\text{ s}$ (Donth, 2001). Additionally, at T_g the τ_R/t_{obs} ratio, the Deborah number, is near unity.

As well as these theoretical concepts, various experimental approaches have been developed to characterize and explain glass transition. As already pointed out, one of the most effective experimental approaches is via DSC studies, which is probably the most sensitive technique to the (small) energy fluctuation during glass transition and relaxation. The glass transition traced by DSC is termed the calorimetric glass transition. T_g can also be measured by thermal expansion or density measurements. The value of T_g for the same glass composition could be slightly different using various measurement methods, even at the same heating rate. It is known that T_g has dynamic characteristic values since it shifts to higher temperatures with an increasing heating rate or cooling rate (Shelby, 2005; Varshneya and Mauro, 2019). To compare the dynamics and physical properties of different glass systems, a standard, unified approach for measuring T_g should be defined. For example, Yue compared the calorimetric glass transition temperature ($T_{g,DSC}$) directly measured by DSC at 10 K min^{-1} with the $T_{g,vis}$ indirectly determined at the viscosity of $\eta = 10^{12}\text{ Pa s}$ (Yue, 2008, 2009), with $T_{g,DSC}$ being defined as the onset temperature of the calorimetric glass transition peak (Fig. 3). As mentioned above, the C_p curve is normally obtained at the standard upscan rate of 10 K min^{-1} (equal to the first downscan rate). He showed that the two sets of T_g values remarkably coincide for oxide glasses (Yue, 2008, 2009). The agreement between $T_{g,vis}$ and $T_{g,DSC}$ can be used for assigning the standard T_g . This allows a direct comparison of the glass transition temperatures among different glassy systems.

Glass Structure

Oxide glasses, such as traditional soda-lime silicate glasses, have network structures composed of SiO_4 tetrahedral building blocks connected by mixed ionic-covalent bonding. Chalcogenide glasses, which contains one or more chalcogens (sulfur, selenium, and tellurium) and exclude oxygen, are built upon two-, three-, and four-coordinated building blocks, which are covalently bonded. Metallic glasses consist mainly of icosahedral units with metallic bonding. Organic polymeric glasses are made through the cross-linking of molecular chains involving van der Waals bonding between chains and covalent intra-molecular bonding. In the recently discovered metal-organic framework glasses, tetrahedral units are connected via coordination bonds. Water can also be quenched into a glassy state and comprises tetrahedral units connected by hydrogen bonds. It is these different types of bonds, resulting from the various electronic structures of the constituent atoms, that lead to different structures, unique state and novel properties of glassy materials (Zheng *et al.*, 2019; Varshneya and Mauro, 2019).

Experimental data and computer simulations of different supercooled liquids and glasses show that their atomic structures below T_g are quite similar to those of their parent supercooled liquid just above T_g (Zanotto and Mauro, 2017; Bykov *et al.*, 2009). Obviously, glasses do not exhibit the ordered crystalline structure as most other ceramic materials but, instead, have a disordered long-range structure with some order at short- and medium-range (3rd–4th neighbors). The most widely used glasses, by far, are oxide glasses, mainly formed from SiO_2 , B_2O_3 , P_2O_5 , As_2O_3 , Sb_2O_3 , GeO_2 , TeO_2 , Al_2O_3 , alkali or alkaline earth oxides, etc. The literature on glass structure is vast because of persistent interest in solid-state chemistry, condensed matter physics, geosciences, and medicine.

Here we aim to highlight a few basic concepts; exemplifying with pure SiO_2 and some of its derivatives. Silicate-based glasses are quite crucial in technology, e.g., optical fibers, electronic screens, architectural materials, and bioactive glasses, but also exist in nature, e.g., obsidian and Libyan Desert glass. Crystalline forms of silica are comprised of a three-dimensionally linked, corner-shared network of SiO_4 tetrahedra (*cf.* Fig. 4(a)). The oxygen links between the Si^{4+} cations ($\dots\text{Si}-\text{O}-\text{Si}\dots$) is called network forming or “bridging” oxygen (BO). When an oxide of another element, typically an alkali or alkaline earth oxide, with +1 or +2 valence, is added to liquid silica, there are too many oxygen anions (O^{2-}) which cannot all bond to two

Fig. 4 Sketch of (a) SiO_4 tetrahedra and (b) two-dimensional view of soda-lime silicate glass structure comprised of a corner-shared network of SiO_4 tetrahedra, bridging (BO) and non-bridging oxygens (NBO), connected with Na^+ and Ca^{2+} cations. Effect of calcium on dissolution and precipitation reactions of amorphous silica at high alkalinity. *Cement and Concrete Research* 87, 1–13, with permission from Elsevier.

tetrahedrally coordinated Si^{4+} cations. As a result, some must be connected to only one oxygen of the SiO_4 group. This oxygen is then called “non-bridging” oxygen (NBO). A two-dimensional view of a SiO_2 – CaO – Na_2O glass showing BO and NBO is shown in **Fig. 4(b)** (Stebbins, 2016). In standard models, exactly two NBO are formed from one BO and one extra O^{2-} ion (see Eq. (7) and **Fig. 5(a)**).

Contrary to Si in binary silicate glasses, B in borate glasses has two coordination numbers with oxygen, $^{\text{III}}\text{B}$, and $^{\text{IV}}\text{B}$. In GeO_2 based glasses, $^{\text{IV}}\text{Ge}$, $^{\text{V}}\text{Ge}$, and $^{\text{VI}}\text{Ge}$ are observed in glass structures. In pure B_2O_3 and GeO_2 glasses, only the lowest coordination states $^{\text{III}}\text{B}$ and $^{\text{IV}}\text{Ge}$ exist. As an alkali oxide is added, NBOs are not necessarily formed as in silicates, but to accommodate the added oxide ion, the coordination of the network cation, e.g., $^{\text{IV}}\text{B}$ and $^{\text{V,VI}}\text{Ge}$ increases (cf. **Fig. 5(b)**). As a result, the modifier cations are coordinated by bridging O atoms, which have partial negative charges, e.g., $[\text{III B-O-IV B}]^{-1/4}$ or $[\text{IV Ge-O-V Ge}]^{-1/5}$. When higher amounts of alkali oxide are added, NBOs form and the coordination of network formers decreases again, finally being dominated by the low-coordination numbers (Stebbins, 2016).

The effects of different cations are usually explained by the “cation field strength,” which is the valence divided by the sum of the cation and oxide ion radii (e.g., $\text{Mg}^{2+} > \text{Ca}^{2+} > \text{Na}^+ > \text{K}^+$) (Brown *et al.*, 2019). Multiple modifier cations (M) present in the melt compete for the formation of small coordination shells with short M–NBO distances. The higher field strength cation is expected to win. This phenomenon is also observed in crystals. For example, Ca^{2+} in crystalline diopside has 4 NBO and 4 BO neighbors, while Mg^{2+} has 6 neighbors, all NBO. Modifier cations in the glass will thus interact with both NBO and BO. The interactions in liquids are dynamic, transient, and liable to be important in breaking BO–Si bonds, activating viscous flow. Mixing of different modifier cations will change the configurational entropy, affecting viscosity curve and thermodynamic variables. For example, contrasting to the crystal, randomized distribution of modifiers in glass and liquid contribute largely to the entropy of melting (Brown *et al.*, 2019; Allwardt and Stebbins, 2004). The 3D scheme for the structure of an yttrium aluminosilicate glass (Y_2O_3 – Al_2O_3 – SiO_2) in **Fig. 6** proves how a broad range of possibilities for obtaining a disordered structure disordering is envisaged. This glass is used in *in situ* radiotherapies, irradiating tumors by the radioactive yttrium isotope (^{90}Y). The ^{90}Y cation can have variable coordination numbers in melts and glasses, which varies in complex ways with composition, temperature, and pressure (Christie and Tilocca, 2012). Therefore, elucidation of structure-property relationship is of the utmost importance in many applications.

Crystallization

Glasses are formed when the kinetic demands of thermodynamic equilibrium are not met by manipulating the chemical composition, sample size, or cooling rate of a melt. Following the most common route of glass formation, i.e., quenching from a melt, any SCL can, in principle, be vitrified with a sufficiently high cooling rate (critical cooling rate) that is enough to avert crystallization. It should be stressed once more that when cooling a liquid, vitrification occurs at a temperature T_g , where the structural relaxation time of the SCL becomes equal to or longer than the experimental observation time. Understanding the role of critical factors that determine the vitrification and crystallization processes, such as glass composition, the structure of the SCL, thermal history, and diffusion processes, is a vital step for the study and development of new materials that readily form glasses, or for the successful progress of glass-ceramic science and technology (Montazerian *et al.*, 2015; Davis and Zanotto, 2017).

Fig. 5 Schematic illustration of a two-dimensional view of a network liquid such as SiO_2 , B_2O_3 , or GeO_2 before and after addition of a network-modifying oxide (M_2O). Here, SiO_4 tetrahedra are shown as planar triangles that share each of their corners. The reaction shown in (a) mostly happens in silicates where the added oxide forms two NBO (dark blue circles) from a connecting bridging oxygen. The negative charges on the NBOs are neutralized by modifying cations. The structural modification shown in (b) is typically observed in germanates or borates. Here, the addition of oxides increases the coordination number of a network cation, e.g., boron coordination changes from 3 to 4. Instead of forming NBO, oxygen bridges between the higher and lower coordinated network cations (light blue circles). In both cases, the M cations (yellow circles) are dispersed to balance the charges on the O atoms. Reprinted from Stebbins, J.F., Wu, J., Thompson, L.M., 2013. Interactions between network cation coordination and non-bridging oxygen abundance in oxide glasses and melts: Insights from NMR spectroscopy. *Chemical Geology* 346, 34–46, with permission from Elsevier.

Crystal nucleation

Nucleation and crystal growth are the two essential stages of crystallization; nucleation is the homogeneous or induced (catalyzed) formation of nanosized critical crystal clusters (nuclei), which is followed by their spontaneous growth becoming crystals. For glass forming compositions, homogeneous nucleation is typically observed in a temperature range (not far from T_g) well below the temperature of maximum crystal growth rates, whereas heterogeneous nucleation rate versus temperature curves are often close and even overlap with those of crystal growth (Fokin *et al.*, 2006).

Crystallization of glasses (or more correctly, of supercooled liquids) is an exothermic process that can be readily detected by thermal analysis techniques, such as DSC and DTA. In a typical DSC curve of a glass, crystallization is displayed as an exothermic peak after the glass transition, T_g , as depicted in Fig. 7. For stoichiometric compositions, the crystallization temperature (T_c), corresponds to the peak temperature in a DSC trace, whereas the onset crystallization temperature is called T_x . Upon continuous heating, in the end, an endothermic peak is a signature of melting (T_L). For off-stoichiometric compositions, two or more crystallization and melting peaks may appear (Fig. 7; Guo *et al.*, 2018).

Detailed knowledge of the thermodynamics and kinetics of crystal nucleation and growth is crucial, either to avoid devitrification or to control the crystallization process. Glass crystallization-related phenomena, including crystal nucleation, induction periods for nucleation, crystal growth, glass stability against devitrification, and glass forming ability are critical parameters in both academic and industrial studies. These phenomena are usually studied by optical and electron microscopy, X-ray diffraction (XRD), nuclear magnetic resonance (NMR), or DSC tests (Guo *et al.*, 2018; Fokin *et al.*, 2006).

In summary, supercooled liquids are metastable against their crystalline (solid) counterparts, the thermodynamically stable state for $T < T_m$. Hence any SCL will tend to crystallize via crystal nucleation which is then followed by spontaneous growth. Nucleation is a stochastic process, hence, after some average time τ_N (which depends on the material's chemical composition and the temperature), one or more critical crystalline nuclei will form in the SCL. Once the nuclei have reached a critical size, crystal growth spontaneously starts and the material solidifies, transforming into a polycrystalline solid.

In steady-state nucleation conditions, which are typically observed above T_g , the average number of nuclei (N_v) per volume (V) equals $N_v = I_{st} \cdot t$, where $I_{st} (m^{-3} s^{-1})$ is the steady-state nucleation rate at the temperature of study. In this condition, the average nucleation time is $\tau_N = (I_{st} \cdot V)^{-1}$. However, for very deep supercoolings ($T \ll T_g$), where the nucleation induction times, t_{ind} , are significant, t_{ind} must be added to $(I_{st} \cdot V)^{-1}$, hence $\tau_N \leq (I_{st} \cdot V)^{-1} + t_{ind}$ (Fokin *et al.*, 2006; Deubener *et al.*, 2017). τ_N and t_{ind} are shown in Fig. 8, which is an example for a N_v vs. time plot in a fixed temperature (the crystal nucleation and growth temperatures are $T_N = 430^\circ C$ and $T_G = 626^\circ C$, respectively). Hence, to estimate τ_N at very deep supercoolings, one has to extrapolate experimental values of steady-state nucleation rates and obtain nucleation induction times, which are typically measured at and above T_g down to very low temperatures. In any case, the nucleation times are always finite; therefore for infinitely long times, all supercooled liquids should crystallize by nucleation and growth (Fig. 8(b)).

Crystal growth

As soon as the nucleation conditions are attained and some nuclei reach the critical size, crystal growth spontaneously proceeds (there is no thermodynamic barrier for crystal growth). The transport of atoms at the interface between the nucleus and the

surrounding SCL matrix is of great importance with regard to kinetic and morphological processes of crystal growth. Three basic models are available to describe crystal growth rates: normal growth, screw dislocation growth, and secondary nucleation or two-dimensional growth (Nascimento *et al.*, 2004, 2011).

During Normal (or Continuous) Growth, the crystal/liquid interface is pictured as rough at an atomic scale. Growth takes place at step sites, which represent a sizable fraction (0.5–1.0) of the interfacial sites. When this fraction does not change appreciably with temperature, the growth rate, $U(T)$, can be expressed as (Nascimento *et al.*, 2004, 2011):

$$U = f \frac{D}{4d_0} \left[1 - \exp\left(-\frac{\Delta G}{k_B T}\right) \right] \quad (8)$$

where f is close to unity, ΔG is the Gibbs free energy, D is the effective diffusion coefficient controlling material transport to the interface, and d_0 is a jump distance (a few Angstrom).

In the Screw Dislocation growth model, the interface is assumed to be smooth but imperfect at an atomic scale. Crystal growth takes place at a few step sites provided by screw dislocations that intersect the interface. The growth rate is also given by Eq. (8), where f is the fraction of preferred growth sites (on the dislocation ledges) at the interface. In this case, $f \ll 1$ is given approximately by $f \simeq (T_m - T)/(2\pi T_m)$ (Nascimento *et al.*, 2011).

In the case of Secondary Surface Nucleation or Two-dimensional growth, the interface is smooth and perfect at an atomic scale and thus free of intersecting screw dislocations and growth sites. Growth then takes place by the formation and growth of new two-dimensional nuclei at the interface (Nascimento *et al.*, 2004, 2011).

In both crystal nucleation and growth, the interplay between an increasing driving force for crystallization, ΔG , and decreasing diffusion coefficient (e.g., increase in viscosity) with decreasing temperature results in a maximum of the $I(T)$ and $U(T)$ curves. The maximum growth rate is usually located at higher temperatures than that of the maximum of the (homogeneous) steady-state nucleation rate (Fig. 9; Schmelzer *et al.*, 2015).

Overall crystallization

The overall crystallization of supercooled liquids occurs by a combination of crystal nucleation and growth. The kinetics of such processes is usually described by a theory independently derived between 1937 and 1941 by Johnson & Mehl, Avrami, and Kolmogorov (JMAK theory) (Fokin *et al.*, 2006). In this approach, the evolution of the volume fraction of the crystalline phase is described as a function of time, accounting simultaneously for nucleation and growth. According to this model, the volume fraction of the new phase (in this case a crystal) is given by Eq. (9) (Shelby, 2005; Varshneya and Mauro, 2019; Šesták and Šimon, 2013).

Table 2 Values of the Avrami exponent (n) for several mechanisms of crystallization

<i>Polymorphic change, interface-controlled growth</i>	<i>n</i>	<i>Diffusion-controlled growth</i>	<i>n</i>
Increasing nucleation rate, 3D	> 4	Increasing nucleation rate, 3D	> 2.5
Constant nucleation rate, 3D	4	Constant nucleation rate, 3D	2.5
Decreasing nucleation rate, 3D	3–4	Decreasing nucleation rate, 3D	1.5–2.5
Zero nucleation rate (nucleation site saturation) 3D	3	Constant nucleation rate, 2D	2
Constant nucleation rate, 2D (plate)	3	Zero nucleation rate, 3D	1.5
Zero nucleation rate, 2D (plate)	2	Constant nucleation rate, 1D	1.5
Constant nucleation rate (nucleation site saturation), 1D	2	Zero nucleation rate, 2D	1
Zero nucleation rate, 1D (needle)	1	Zero nucleation rate, 1D	0.5

(Eds.), Thermal Analysis of Micro, Nano- and Non-Crystalline Materials: Transformation, Crystallization, Kinetics and Thermodynamics. Netherlands: Springer.

$$\alpha(t) = 1 - \exp \left\{ -g \int_0^t I(T) \left[\int_{t'}^t U(T) dt' \right]^3 dt \right\} \quad (9)$$

where g is a shape factor that depends on the shape of crystals. If the nucleation (I) and growth (U) rates are constant throughout the transformation, and the crystals are spherical, Eq. (9) can be rewritten as:

$$\alpha(t) = 1 - \exp \left[-\frac{gIU^3t^4}{4} \right] \quad (10)$$

When the number of growing crystals, N_0 , does not change with time (typical for fast heterogeneous nucleation on a finite number of active sites, or from quenched-in, athermal nuclei), Eq. (9) transforms to:

$$\alpha(t) = 1 - \exp[-gN_0U^3t^3] \quad (11)$$

Avrami proposed that, in the general case, the following relation should be used:

$$\alpha(t) = 1 - \exp[-Kt^n] \quad (12)$$

where K represents the so-called rate constant, and n is the Avrami coefficient. In typical applications, Eq. (12) is used in the form

$$\ln(-\ln(1 - \alpha)) = \ln K + n \ln t \quad (13)$$

The values of K and n can be estimated by fitting the experimental data of $\alpha(t)$ (crystal volume fraction of isothermally heat-treated glass) to Eq. (13). Thus, the coefficient K includes I and U , or N_0 and U .

In Eq. (13), n is called the Avrami coefficient, and depends on both nucleation and growth mechanisms, as shown in Table 2. The knowledge of that coefficient is very helpful to understand the mechanism of phase transformation at any given temperature (Illeková and Šesták, 2013).

The JMAK theory has been used in numerous studies to analyze experimental data and determine the degree of crystallinity as a function of time in both isothermal and non-isothermal heat treatments of glass systems. Emphasis is usually given to determining the so-called Avrami coefficient $m = n + 1$ obtained from the slopes of experimental $\ln[-\ln(1 - \alpha)^{-1}]$ versus $\ln(t)$ plots. However, there is frequently some uncertainty in such analyses, because different combinations of nucleation and growth laws may lead to the same Avrami coefficient. For this reason, a separate investigation of the growth kinetics may be required to reach definite conclusions. It is important to underline that the JMAK theory, as given by Eqs. (10)–(12), does not apply to non-isothermal processes. These three equations are derived from the assumption of constant nucleation and growth rates, which are not achieved in non-isothermal processes. Therefore, in non-isothermal cases, the general relationships, Eq. (9), must be used to describe overall crystallization (Gutzow and Schmelzer, 1995).

Finally, we should emphasize that the extremely good glass-forming liquids known so far – $\text{Na}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 6\text{SiO}_2$ (albite) and B_2O_3 – will also crystallize if they are subjected to sufficient long thermal treatment. This is because their maximum homogeneous nucleation rates are located well below their glass transition temperatures, in a region of very high viscosity, which leads to extremely long nucleation time-lags and low nucleation rates (Zanotto and Cassar, 2017). However, under adequate conditions, they should crystallize.

Summary and Conclusions

It is estimated that more than 10^5 inorganic glasses have already been made (Zanotto and Coutinho, 2004), and billions of others could still be made, however, crystallization (solidification) must be avoided for vitrification. Hence only a small fraction of the possible compositions can be effortlessly vitrified.

Are glasses solids or liquids? We defend that glasses are neither solids nor liquids; instead, they display ambivalent properties: of solids – they ring, resonate, scratch and fracture – and liquids, they have an identical structure as their parent liquids, and also show the unique property of spontaneously relaxing towards the SCL state, even without the influence of any external stress. Moreover, the glassy state itself cannot be expressed as any linear combination of supercooled liquid states.

All glasses are trapped in a frozen, transient state; they will relax toward the supercooled liquid state and ultimately crystallize. The relaxation and crystallization times strongly depend on their chemical composition and on how far below its T_g the glass is being studied. If a glass is being tested only a few degrees below its T_g , relaxation and crystallization take place in a few minutes or hours; whereas, at several hundred degrees below T_g , these processes will only take place in geological time scales. Therefore, in our opinion, the glassy state is a unique non-ergodic, non-equilibrium, non-crystalline state of matter that continuously relaxes and finally crystallizes. The modern definition of glass revised and discussed here can be applied to all types of glasses.

Acknowledgments

The authors are grateful to the São Paulo Research Foundation (FAPESP, # 2013/07793-6) – CEPID/CeRTEV – for the financial support of this work and the post-doctoral fellowship granted to Maziar Montazerian (# 2015/13314-9). We are also indebted to Prof. John C. Mauro for his most useful insights when we co-authored [Zanotto and Mauro \(2017\)](#), which “nucleated” this chapter. This chapter is thus an extended version of [Zanotto and Mauro \(2017\)](#).

Glasses: Alkali and Alkaline-Earth Silicates

Benjamin JA Moulton, Federal University of São Carlos, São Carlos, São Paulo, Brazil

Grant S Henderson, University of Toronto, Toronto, ON, Canada

© 2021 Elsevier Inc. All rights reserved.

Introduction

When alkali (Li, Na, K, Rb, Cs) and alkaline-earth (Be, Mg, Ca, Sr, Ba) cations are added to pure SiO_2 glass they disrupt the fully continuous network of corner linked SiO_4 tetrahedra. The oxygens shared between the Si atoms, termed bridging oxygens (BO), are broken to form what are termed non-bridging oxygens (NBO). Ideally, for every alkali cation 1 NBO is formed and for every alkaline-earth cation 2 NBOs are formed (cf., [Henderson and Stebbins, 2021](#)). The NBO is attached to one Si atom and charge balanced by the added cation now called a charge compensator. Elements that break BOs to form NBOs in the glass are termed network modifiers whereas elements that tend to generate BOs, like Si and other high field strength cations are termed network formers. The SiO_4 tetrahedra can themselves be classified on the basis of the number of BOs within each tetrahedron. These are termed Q^n species (where n = the number of BOs attached to the Si atom) and depending upon the number of alkali or alkaline-earth cations added to the glass, there can be Q^4 , Q^3 , Q^2 , Q^1 and Q^0 tetrahedra formed (See [Fig. 1](#)). Furthermore, it has recently been found that more than one type of BO may exist in alkali-silicate glasses. The BO can itself be bonded to one or more of the alkali cations (termed MBO) (see [Nesbitt et al., 2015a](#); [Sukenaga et al., 2017](#); [O'Shaughnessy et al., 2017c, 2020](#); [Henderson and Stebbins, 2021](#) and references therein). Such bonds are common in silicate crystal structures such as $\alpha\text{-Na}_2\text{Si}_2\text{O}_5$ where the structure is exclusively Q^3 tetrahedra in chains. The Q^3 tetrahedra have 2 MBOs and one regular BO ([Pant and Cruickshank, 1968](#)). Logically, such bonds must be present in glasses because while one Na atom produces 1 NBO and acts as a charge compensator, its coordination number is around 5 ([Gagné and Hawthorne, 2016](#)). Some of these bonds must therefore be to bridging oxygens regardless of whether or not the alkalis are heterogeneously or homogeneously distributed throughout the glass network. Whether or not a bond with the BO forms or the cation simply closely approaches the BO remains a challenging issue. Extensive molecular orbital calculations do show that such bonds are likely and energetically favored ([Gibbs, 1982](#); [Gibbs et al., 1997, 2008](#)). The effects of a modifier cations' influence on BO remains a research area of considerable potential, especially with respect to phase separation and crystallization. Finally, in aluminosilicate glasses another type of oxygen may form: the oxygen tricluster (See [Fig. 1](#)). Oxygen triclusters were first suggested to occur in Al_2O_3 rich glasses by [Lacey \(1963\)](#). It is defined as a group of three network cations, each of which has three or four oxygen first neighbors which share a single oxygen (cf., [Henderson and Stebbins, 2021](#)). They are unlikely to be present in alkali or alkaline-earth silicate glasses.

This chapter starts with discussion of the key historical insights into the glass structure of alkali silicates in contrast to pure silica glass. The chemical reactions occurring when alkali or alkaline-earth cations are introduced into the glass are covered before discussing phase separation, a common phenomenon at low modifier contents. An overview of each of the alkali-silicate binaries is given before discussion of the mixed alkali effect (MAE) when two modifier cations are introduced into the silicate network. Each of the alkaline-earth silica binary glasses are then reviewed. Both alkali and alkaline-earth silicate glasses, and their crystalline counterparts, are used extensively in industrial applications and are often the base glass to which other cations are added to develop numerous applications from window glass, to fiber optics, to biomaterials and more (see below). These applications are briefly discussed.

Silicate Glasses

The structure and physical properties of alkali-containing glasses in general exhibit a dependence upon the type of alkali present in the glass. Different alkali cations have been shown to have a number of effects on changes in activation energy of viscous flow, molar volume and thermal expansion (cf. [Stebbins, 1995](#)), for example. The first diffraction study of an alkali silicate glass was by [Warren and Loring \(1935\)](#), and [Warren and Biscoe \(1938\)](#) on Na-silicate glass. Their diffraction profiles showed a continuous change in appearance with increasing sodium content. They concluded that the structure of sodium silicate glass consisted of tetrahedrally coordinated silicon atoms surrounded by four oxygen atoms, with a bond distance of 1.62 Å. Some of the oxygen atoms are BOs and some NBOs. They did not observe discrete molecules such as SiO_2 , Na_2O , $\text{Na}_2\text{Si}_2\text{O}_5$ or Na_2SiO_3 . The sodium ions are surrounded by six oxygen atoms with an average bond-length of 2.35 Å and arranged in random holes throughout the silicon-oxygen network. It was also observed that as the sodium content increased, the number of non-bridging oxygen atoms increased. In describing the sodium silicate structure, [Warren and Biscoe \(1938\)](#) employed the continuous random network (CRN) model of [Zachariasen \(1932\)](#) to fit the observed data. The random network model accounts for the replacement of a BO with two NBOs upon the addition of each network-modifier oxide, M_2O ($\text{M} = \text{Li, Na, K, Rb, Cs}$). The negative charge of the NBO is balanced by the positively charged alkali cation in order to maintain charge neutrality and it assumes that the alkali atoms are distributed randomly through the network. Subsequent studies by [Greaves et al. \(1981\)](#) and [Greaves \(1985\)](#) suggested that the alkali atoms are heterogeneously distributed in alkali-silicate glasses and the modified random network (MRN) model was

Fig. 1 Various Q^n species: NBO (peach), BO (red), MBO (green) and an oxygen tricluster (red with yellow circle). (a) Q^0 tetrahedron with no BO, (b) Q^1 with 1 BO, (c) Q^2 with 2 BO, (d) Q^3 with 3 BO, (e) Q^4 with 4 BO, (f) Oxygen tricluster (red) being shared with 3 AlO_4 tetrahedra (light blue), (g) partial structure of α - $Na_2Si_2O_5$ showing Q^3 tetrahedra with regular BO (red) and MBO (green) with Na (yellow) attached.

developed. Here the alkali atoms (Na and Ca in his studies) are concentrated around channels that are distributed randomly throughout a more silicate-rich network (see Fig. 2). See Le Losq *et al.* (2019), Greaves (2021) for more current descriptions of this model.

This widely accepted model requires that alkali cations be heterogeneously distributed within a SiO_2 rich network. However, it should be noted that many studies conclude that alkalis are homogeneously distributed throughout the SiO_2 network (e.g., Lee and Stebbins, 2003; 2009; Angeli *et al.*, 2011). Furthermore, the bulk of the experimental work has been on sodium silicate glasses which undergo phase separation. One should keep in mind the question of whether or not the channels are truly representative of the glass structure, or are a result of insipient phase separation or micro segregation due to synthesis and quench conditions (see below for phase separation details).

The way the tetrahedra are linked together constitutes the intermediate-range structure (IRO) or medium-range structure (MRO). Silica glass is primarily composed of rings of between 3- to 7 SiO_4 tetrahedra (cf., Henderson, 2005; Le Losq *et al.*, 2019) with a mean ring size around 6. These rings have in turn been classified as being similar to those found in the crystalline polymorphs of SiO_2 i.e., cristobalite-like, and/or tridymite-like with various proportion of each e.g., 2/3 tridymite, 1/3 cristobalite (Henderson *et al.*, 1984); α -cristobalite/ β -cristobalite (Sonneville *et al.*, 2013). The rings and the extended glass network are composed of SiO_4 tetrahedra (all Q^4) that are fully interconnected through the BOs at the corners of the tetrahedron. The average Si-O bond distance is around 1.61 Å, the O-O distance 2.65 Å, and the first Si-Si distance at around 3.10 Å. The average Si-O-Si angle is around 147°–152° as determined from a number of different techniques (See Henderson and Stebbins, 2021). It is not around 144° as calculated by Mozzi and Warren (1969) (see discussion in Neufeind and Liss, 1996; Henderson, 2005; Eckert, 2018; Henderson and Stebbins, 2021, for an explanation).

The Relationship Between Oxygen and Q^n Speciation

Often the Q^n species distribution in alkali- and alkaline-earth silicate glasses is calculated from their chemical composition (cf., Le Losq *et al.*, 2019) and/or estimated by determining the NBO/T ratio where T = moles of Si (or any tetrahedral network former) and NBO represents the moles of non-bridging oxygen in a glass (Mysen and Richet, 2019). The NBO/T gives an indication of the degree of polymerization. It can be readily calculated for *crystalline materials* but is somewhat misleading for glasses and melts (see below). In addition, it is also widely held that the Q^n species distributions within a glass are given by the disproportion reaction:

Fig. 2 Examples of a modified random network: (a) showing percolation channels with MBOs present near the channels, atom labeled “1” is an NBO, “2” and “3” are BOs with a Na attached (MBO), “4” is a regular BO shared between two Si atoms; (b) Results of a computer simulation showing “dynamic trajectories” of Na atoms. Red are oxygen atoms and the larger yellow atoms are Si. Reprinted with permission from: (a) Nesbitt, H.W., Henderson, G.S., Bancroft, G.M., Ho, R., 2015a. Experimental evidence for Na coordination to bridging oxygen in Na-silicate glasses: Implications for spectroscopic studies and for the modified random network model. *J. Non-Cryst. Solids* 409, 139–148. copyright 2015. (b) Meyer, A., Horbach, J., Kolb, W., Kargl, F., Schober, H., 2004. Channel formation and intermediate range order in sodium silicate melts and glasses. *Phys. Rev. Lett.* 93, 027801. copyright 2004.

As [Le Losq et al. \(2019\)](#) point out, this reaction is in fact an equilibrium reaction as shown in [Eq. \(2\)](#), which is influenced by a number of factors including the ionic field strength of the cations and fictive temperature of the glass:

The mass balance equation for [Eq. \(2\)](#) is given by:

$$K = [Q^{n-1}][Q^{n+1}]/[Q^n]^2 \quad (3)$$

While this disproportion reaction does generally hold for glasses, there are some caveats. The apparent disproportionation reaction in [Eq. \(1\)](#) yields $[Q^{n-1}] = [Q^{n+1}]$ from stoichiometry; but [Eq. \(3\)](#) shows that $[Q^{n-1}]$ does not have to equal $[Q^{n+1}]$, as long as $[Q^{n-1}][Q^{n+1}] = \text{a constant } (K[Q^n]^2)$. In addition, [Eq. \(2\)](#) ignores polymerization and depolymerization reactions that occur on melting (cf., [Nesbitt et al., 2017c](#); [Henderson and Stebbins, 2021](#)) and secondly, many published glass compositions have not been determined experimentally, but are based on the “as made” nominal compositions which may or may not be accurate, and thirdly, it presumes tetrahedral coordination of the network formers and becomes increasingly inaccurate as T cations take on higher coordinations, especially five- and six-fold configurations.

Crystalline SiO_2 , $\text{Na}_2\text{Si}_2\text{O}_5$, Na_2SiO_3 , $\text{Na}_6\text{Si}_2\text{O}_7$, and Na_4SiO_4 have NBO/T ratios of 0.0, 1.0, 2.0, 3.0, and 4.0, respectively. For binary alkaline-earth crystals such as enstatite (MgSiO_3) and forsterite (Mg_2SiO_4) the NBO/T ratios are 2 and 4, respectively. Such a stoichiometric relationship (1 alkali = 1NBO, 1 alkaline-earth = 2 NBO) does not hold for melts and glasses because polymerization and depolymerization reactions occur on melting of crystals (cf., [Nesbitt et al., 2017b, 2020](#)). Melting of Na_2SiO_3 crystals which only contain Q^2 species produces a melt that contains Q^1 , Q^2 and Q^3 species (with concentration of $Q^3 > Q^1$) (cf., [Richtel et al., 1996](#); [Nesbitt et al., 2017b](#)) as suggested by [Eq. \(1\)](#). However, since Q^3 units have been produced from Q^2 species there has been a polymerization reaction ([Nesbitt et al., 2020](#)) and this is given by:

or more generally as:

Polymerization reactions such as shown in (4) and (5) produce a third oxygen species, free oxygen (FO) or O^{2-} (see [Nesbitt et al., 2011](#); [Moutjoy, 2007](#); [Henderson and Stebbins, 2021](#)). Some alkali or alkaline-earth cations will be bound to O^{2-} (e.g., Na_2O , CaO) rather than to NBOs. The stoichiometric relationship between the NBO and network modifier in the binary glasses does not hold and any calculation of NBO/T will be overestimated, and any nominal Q^n species distribution will be incorrect and becomes increasingly problematic as the silica content decreases. One of the major issues in the literature is that many researchers assume their calculated NBO/T values to be correct and fit their experimental nuclear magnetic resonance (NMR) and Raman data to match their NBO/T values. This leads to a high degree of inaccuracy with regard to Q^n species distributions and large amounts of

Fig. 3 Phase separation showing the nucleation and growth mechanism in 5BaO-95SiO₂ glass. Light colored Ba-rich spheres form within a Si-rich matrix glass. Righthand HAADF-STEM image shows the effects of irradiation and the mobility of the Ba-rich glass. Reproduced with permission from Gueguen, Y., Houizot, P., Célarié, F., *et al.*, 2017. Structure and viscosity of phase-separated BaO-SiO₂ glasses. *J. Am. Ceram. Soc.* 100 (5), 1982–1993.

contradictory data in the literature. An example of this is the $2Q^2$ peak assignment of Maekawa *et al.* (1991) for their K₂SiO₃ glass. Maekawa *et al.* (1991) fit their NMR data to match a calculated NBO/T value of 2.0 which was substantially different from their experimentally determined values of 2.44 and 1.44 (depending upon whether their four fitted NMR peaks were assigned to Q^0 – Q^3 or Q^1 – Q^4 respectively) (cf., Sawyer *et al.*, 2015). The $2Q^2$ peaks are necessary to get the NBO/T values to match the calculated value of 2.0. A consequence of this assignment is that the literature has many studies using the Maekawa *et al.* (1991) $2Q^2$ peak assignment to justify the presence of $2Q^2$ peaks in other types of fits including Principle Component Analysis (PCA) fits and starting assumptions (cf., Zakaznova-Herzog *et al.*, 2007).

In summary, Q^n species abundances or NBO/T cannot be accurately calculated from bulk melt or glass compositions, contrary to popular belief and practice. For a composition such as Mg₂SiO₄ where the calculated NBO/T is 4.0 the experimentally determined NBO/T value is around ~ 3.2 – 3.6 (cf., Nesbitt *et al.*, 2020). The Q^n distribution must be calculated from experimental Q^n species abundances (see Table 1, footnote 1 of Nesbitt *et al.*, 2020 for the calculation) or by direct measurement of NBO (e.g., Nesbitt *et al.*, 2011).

The presence of FO remains a contentious issue with many people simply refusing to accept its existence despite significant evidence that such a species exists (cf., Nesbitt *et al.*, 2015b; Lee and Kim, 2015). In addition, it is clear that even in these small amounts FO plays a critical role in the melting and crystallization of glasses (Nesbitt *et al.*, 2011, 2017b, 2018, 2020).

While the concept of alkali modifiers, network formers and the MRN has proven useful it has ignored any potential interaction between the modifiers and BOs. The concept of MBOs and their impact on glass properties and behavior has essentially been completely neglected but for a few studies (Kamitsos and Risen, 1984; Bakk *et al.*, 2012; Nesbitt *et al.*, 2015a, 2018; O'Shaughnessy *et al.*, 2017, 2020; Salmon *et al.*, 2019). It remains an area which requires study.

Phase Separation

Phase separation or metastable immiscibility occurs in Li₂O-SiO₂ from 0 to 33.3 mol% Li₂O, in Na₂O-SiO₂ glasses from 0 to 26 mol% Na₂O, CaO-SiO₂ between 1.8 and 21.8 mol% CaO (Tewhey and Hess, 1979), SrO-SiO₂ between ~ 2 and 30 mol% (Greig, 1927), and in BaO-SiO₂ between 0–28 mol% BaO (Levin and Block, 1956; Charles, 1966; Levin, 1967; Haller *et al.*, 1974; Hudon and Baker, 2002a,b; Seward *et al.*, 1984a,b). Rb₂O-SiO₂ and Cs₂O-SiO₂ glasses do not appear to exhibit phase separation. K₂O-SiO₂ glasses also appear to have some immiscibility field but the extent remains somewhat unclear (Charles, 1966; Gupta and Mishra, 1969; Haller *et al.*, 1974; Kawamoto and Tomozawa, 1981) if it occurs at all (Borisova and Ushakov, 1998). Phase separation has not been studied in BeO-SiO₂ glasses. In all cases of immiscibility, if the melt is quenched too slowly the resulting glass appears opalescent due to formation of two glass phases which causes light scattering at their interfaces. Fast quenching can avoid the onset of the immiscible behavior of much of the metastable immiscibility range.

For Li-silicate glasses from 0 to 40.7 mol% Li₂O, lithium disilicate is the stable phase and >40.7 mol% Li₂O, lithium metasilicate is stable (Sycheva and Kostyreva, 2014). In addition, other unidentified metastable Li-silicate phases may also be present (cf., Soares *et al.*, 2003). Non-stoichiometric, Ba-rich phases have also been reported in the BaO-SiO₂ system (e.g., Moulton *et al.*, 2019). Sodium-silicate glasses exhibit similar metastable immiscibility to the Li-silicate glasses. However, the immiscibility range is only up to around 26 mol% Na₂O (near the Na₂Si₃O₇ composition) (Haller *et al.*, 1974). Like the Li-silicate glasses the stable crystalline phases are Na₂Si₂O₅ and Na₂SiO₃.

Hudon and Baker (2002a) investigated miscibility gaps in 41 binary silicate systems. They concluded that phase separation in these systems was due to coulombic repulsion between poorly screened cations. The cations being bonded to BO (MBO), which are strongly polarized towards Si, and by regular NBO. They found that for cations with ionic radii ≥ 87.2 pm, and with coordination numbers (CN) > 5 , the size of their miscibility gaps had a linear dependence on ionic potential. For cations > 26 pm to 87.2 pm (CN between 4 and 5 or above) their miscibility gap does not increase linearly with increase in ionic potential. Cations which have variable crystal field splitting energies (e.g., transition metals) and those with lone pair electrons (e.g., Pb^{2+} , Te^{4+}) also display unique phase separation behavior though these are dealt with elsewhere (Hudon *et al.*, 2004). Phase separation occurs through one of two mechanisms, either nucleation and growth or spinodal decomposition (James, 1975). The former mechanism produces spheres, nuclei, of one liquid that grows within a matrix of a second liquid (Fig. 3) whereas spinodal decomposition produces a diffuse interface between the two liquids. Phase separation and liquid immiscibility are fundamental processes in silicate liquids for both producing large scale differentiation of magmas (Charlier *et al.*, 2011; Charlier, 2015; Hou and Veksler, 2015), and producing kitchenware worldwide (Stookey, 1959).

$\text{Li}_2\text{O-SiO}_2$ Glasses

Lithium silicate glasses behave differently to the other alkali glasses. A similar effect is observed for Be relative to the alkali-earths (see below). These differences appear to be related to the small atomic size and field strength of these cations relative to their other group members. Lithium silicate glasses contain Q^2 , Q^3 and Q^4 species but with significantly more Q^2 and Q^4 compared to the other alkali silicate glasses. In addition, it has a preference for forming Q^2 species at low alkali concentrations relative to the other alkalis with this Q^2 -forming tendency decreasing with increasing cation size and cationic potential (Z/r) of the alkali (cf., Matson *et al.*, 1983; Schramm *et al.*, 1984; Grimmer *et al.*, 1984; Dupree *et al.*, 1986; Maekawa *et al.*, 1991; Hannon *et al.*, 1992; Soltay and Henderson, 2005a,b; O'Shaughnessy *et al.*, 2020, for example).

Xu *et al.* (1989) observed in a series of high Li-silicate glasses (24–33.3 mol% Li_2O) the presence of Q^4 , Q^3 and Q^2 species with the presence of significant Q^2 species. They suggested that the NBO distribution was not random and consistent with the MRN model of silicate glasses. Umesaki *et al.* (1993) also investigated high Li_2O glasses and obtained Q^4 to Q^1 species with the Q^n distribution in agreement with the results of Dupree *et al.* (1990). Umesaki *et al.* (1993) also found lithium atoms to be coordinated by 2–3 oxygen atoms, in accordance with Hannon *et al.* (1992). However, Uhlig and colleagues (Uhlig *et al.*, 1996a,b,c) found that Li is 4-fold coordinated in high Li_2O content glasses. In addition, Kitamura *et al.* (2000) observed that at high pressure (P) the Si-O bond lengthened with increasing P up to 6 GPa, and Buchner *et al.* (2014) noted that distortion of the SiO_4 tetrahedron is the main structural change observed in Li-silicate glasses up to 6 GPa. At 7.7 GPa polyamorphism was observed (Buchner *et al.*, 2014).

Du and Corrales (2006) have performed ab initio molecular dynamics to investigate Li-disilicate glass and melt. Their calculated bond distances and Q^n species distributions are in agreement with experimental studies (cf., Umesaki *et al.* 1993; Xu and Stebbins, 1995). Uchino and Yoko (1999) performed similar simulations on both Li- and Na-silicate glasses. They found that the coordination number of sodium was larger than that of lithium in the glasses. Uchino and Yoko (1999) reported that the coordination environments are influenced by the electronegativities of the alkalis: The Li-O bond overlap is considerably larger than the Na-O bond. This suggests that the Li-NBO bonds have strong covalent interactions and are more likely to interact with NBOs, while sodium is more likely to interact with both BO and NBO atoms.

$\text{Na}_2\text{O-SiO}_2$ Glasses

Misawa *et al.* (1980) reported lengthening of the alkali silicate Si-O bond in comparison to pure vitreous silica; 1.63 and 1.62 Å for the sodium and lithium silicates, respectively. They also noted that the Si-O bond length increases with added alkali. This was later confirmed through other studies (cf. Henderson, 1995). Misawa *et al.* (1980) also reported an observed Si-O bond weakening and the presence of Q^3 tetrahedra as observed by Warren and Bischoe (1938). Greaves *et al.* (1981) and Greaves (1985) data revealed that the structures of sodium silicate glasses remain relatively similar and minor differences in the EXAFS data were attributed to the addition of network modifiers and the distribution of Q^n species. The Na EXAFS spectra showed a higher frequency of oscillations than the Si EXAFS, indicating that the Na-O bond is longer than the Si-O bond and that different bonding interactions are taking place.

In agreement with previous studies, Henderson (1995) reported that sodium silicates were locally structured with tetrahedrally coordinated silicon environments. However, the Si-Si bond distributions decreased with addition of Na_2O , and the contribution from multiple scattering beyond the second coordination sphere increased. This suggested that a degree of intermediate-range ordering was taking place with the addition of sodium. Furthermore, there was an increase in the Si-O bond distance with the addition of sodium, from 1.61 ± 0.02 Å for amorphous silica to 1.66 ± 0.02 Å for 30 mol% Na_2O . This change in bond distance indicated that the network depolymerization effect on the Si-O bond dominated over increased numbers of non-bridging oxygen atoms (Si-NBO bonds are shorter than Si-BO bonds). Above 30 mol% Na_2O the Si-O bond distances decreased owing to the dominating NBO distribution. This relationship suggested that the micro segregation of network modifiers from network formers is significant for sodium concentrations > 30 mol%.

Hoppe *et al.* (1995) noted that their X-ray (XRD) and neutron diffraction (ND) data indicated 2 types of Na sites in their sodium silicate glasses (23.5 and 33 mol% Na_2O) with Na-O distances of 2.25 and 2.55 Å. They concluded that the Na sites were

similar to those found in α -Na₂Si₂O₅ (Na in 5-fold coordination with 4 Na-NBO and 1 Na-BO bonds) and β -Na₂Si₂O₅ (6-fold coordination with 4 Na-NBO and 2 Na-BO bonds). Zotov and Keppler (1998) investigated sodium tetrasilicate glasses around the glass transition ($\cong 773$ K) and concluded there is little change in the short and intermediate-range structure of melt versus glass at this temperature.

The alkali-silicate glasses have been extensively investigated using NMR and Raman spectroscopy (see Henderson and Stebbins, 2021; Le Losq *et al.*, 2019 and references therein). de Jong *et al.* (1981) reported that both lithium and sodium cations tend to have a bimodal distribution throughout the silicate network and form alkali clusters whereas potassium, rubidium and cesium cations exhibited more uniform distributions. They also observed that lithium silicates are more stable with a Q⁴-Q² distribution rather than a Q³-Q³ arrangement. This results in clustering of lithium pairs around the SiO₄ tetrahedra. These conclusions were supported by Matson *et al.* (1983) who investigated $xM_2O \cdot (100 - x)SiO_2$ glasses (M = Li, Na, K, Rb, Cs and $x = 0, 5, 10, 15, 20, 25, 30$) with Raman spectroscopy. Significant changes were observed in the Raman spectra with the addition of small amounts of alkali oxides and high-frequency spectral features were useful in interpreting the distribution of Qⁿ species. No attempt was made to curve fit the spectra. Recently, O'Shaughnessy *et al.* (2020) re-examined the compositions of Matson *et al.* (1983) also using Raman spectroscopy. O'Shaughnessy *et al.* (2020) fit the high frequency Raman envelope characteristic of Qⁿ species. Their approach is novel, and indicates that there are multiple types of Q⁴, Q³ and Q² species present. Unlike previous studies that have fit this envelope, O'Shaughnessy *et al.* (2020) use a consistent approach to band shape and band assignments and they discriminate bands where the alkali is near a BO (MBO) and is not near a BO (NBO). They find that, with increasing alkali-oxide, the proportion of Qⁿ species affected by nearby alkali cations increases. Furthermore, there are 2 Q⁴ bands present in the high frequency envelope which merge at 20 mol% alkali oxide for all binaries.

Molecular dynamics (MD) simulations have been extensively performed on a wide variety of alkali-silicate glasses in order to probe the chemical and physical behavior and properties of alkali-silicate glasses (e.g., Huang and Cormack, 1991, 1992; Smith *et al.*, 1995; Vessal *et al.*, 1996; Du and Cormack, 2004, 2006; Ispas *et al.*, 2001, 2010; Bauchy and Micoulaut, 2011; Jabraoui *et al.*, 2016; Baral *et al.*, 2017, 2019; Zhen *et al.*, 2020).

MD simulations by Huang and Cormack (1991) showed Na and K cations to be positioned around NBOs, forming regions rich in Q³ species and creating extended silica rich regions with alkali rich channels contained within them. This was consistent with the MRN model (Greaves *et al.*, 1981; Greaves, 1985). Huang and Cormack (1991) also proposed that the percentage of Qⁿ species (Q², Q¹ and Q⁰ species) is reflected in the distribution of the alkali and NBO clusters, with Q³ species dominating at the disilicate composition. Their simulations showed that the alkali and NBO distribution is more uniform for potassium silicate glasses than sodium silicate glasses. This suggests that different alkali cations have different behavior in modifying the network structure. Further analysis revealed the NBO per silicon distribution to decrease in order of Li > Na > K.

Smith *et al.* (1995) supported the formation of Q³ and silica rich regions as observed by Huang and Cormack (1991, 1992). Smith *et al.* (1995) also observed the structure of sodium silicate glass to be inhomogeneous with a non-uniform distribution of sodium ions and clustering of sodium around the NBO atoms. With increasing amounts of sodium, the sodium rich and silicate rich regions were observed to extend three-dimensionally. Vedishcheva *et al.* (1995) also found that the cation arrangement within the network is non-uniform, and exists as clusters of negatively charged non-bridging oxygen atoms attracting the positively charged network modifying cations, and vice versa. They also suggested that the tetrahedral Q⁴ species tend to accumulate in silica-rich regions.

Uchino and Yoko (1999) investigated sodium and lithium silicate glasses by ab initio molecular orbital calculations. They reported that in sodium silicate glasses, the Si-O (BO) and the Si-O (NBO) bonds were longer and shorter, respectively, than the corresponding lithium silicate bond-distances.

Furthermore, coordination-numbers for sodium were higher than for lithium in silicate glass. Uchino and Yoko (1999) concluded that Li-O bonds have greater bond-overlap and greater covalent interactions than Na-O bonds and this results from increased covalent interactions in sodium silicate versus lithium silicate glasses. This in turn results in an increase in the tendency for alkali cations to interact with bridging and non-bridging atoms. Uchino and Yoko (1999) concluded that both the size and molecular orbital interactions between alkali cations and the surrounding oxygen atoms determined alkali coordination. Bauchy and Micoulaut (2011) studied the dynamics of Na₂O-3SiO₂ composition glasses and suggested that there were different diffusion regimes with increasing density at fixed temperature. They observed conversion of percolation channels to small pockets once the density increased. The most recent simulations (Ispas *et al.*, 2001, 2010; Jabraoui *et al.*, 2016; Baral *et al.*, 2017, 2019; Zhen *et al.*, 2020) have tended to focus on determining spectroscopic behavior by using classical molecular dynamics (MD) to generate a hypothetical glass structure followed by ab initio MD to determine various spectroscopic responses (i.e., Raman, Infrared (IR), NMR) of the structure.

X-ray photoelectron spectroscopy (XPS) has also been used to investigate sodium and potassium silicate glasses (e.g., Nesbitt *et al.*, 2011, 2015a, 2017c; Sawyer *et al.*, 2015). XPS using an Al K α source (1486 eV photons) has an analysis depth of about 50 angstroms, so it is often used as a surface probe. However, it has been used successfully for bulk analysis of many silicates, and it yields good bulk analyses if precautions are taken. With the Kratos XPS instruments, reproducible O 1 s spectra of pristine fractured glass surfaces can be obtained in a few minutes with excellent resolution of the BO and NBO + O²⁻ peaks (Nesbitt *et al.*, 2011, 2015a,b). The %BO can be obtained easily and precisely from good fits to the spectra; and any surface modification from the x-ray beam can be corrected by plotting the %BO against time, and extrapolating the %BO to $t = 0$. The observed %BO can be compared with that expected theoretically for no O²⁻ (complete conversion of BO to NBO by the Na₂O from the reaction $BO + O^{2-} \rightarrow 2NBO$), and there is excellent agreement between experiment and theory for the low Na glasses (25 and 30 mol%

Na_2O) where the O^{2-} will be much less than 1%. This agreement is excellent evidence that the %BO values from XPS are not only precise, but accurate. For the higher mol% Na_2O glasses (e.g., 45, 50, 55%), the %BO values are larger than that expected for the “complete conversion” values, showing that there is appreciable O^{2-} . For example, for the 50 mol% Na_2O glasses, the mol% O^{2-} is $4\% \pm 2\%$ (Nesbitt *et al.*, 2015b), and this value is in good agreement with the ^{29}Si NMR (Nesbitt *et al.*, 2011, 2015a,b) and the Raman results (Bancroft *et al.*, 2018). The broadened BO peaks also give good evidence for the presence of MBO (Nesbitt *et al.*, 2015a, 2017c).

$\text{K}_2\text{O-SiO}_2$ Glasses

Numerous diffraction (Meneau *et al.*, 2001; Majérus *et al.*, 2004), Raman (Zakaznova-Herzog *et al.*, 2007; Malfait *et al.*, 2007a; O’Shaughnessy *et al.*, 2020), NMR (Sen and Youngman, 2003; Malfait *et al.*, 2007b; Davis *et al.*, 2010; Stebbins and Sen, 2013; Sawyer *et al.*, 2015; Stebbins and Bista, 2019), EXAFS (Kamijo *et al.*, 1996) and XPS (Sawyer *et al.*, 2015) studies have been performed on $\text{K}_2\text{O-SiO}_2$ glasses. The medium-range structure of potassium silicate glasses (5–35 mol% K_2O) was studied by Meneau *et al.* (2001) using wide-angle X-ray scattering (WAXS) and ^{29}Si NMR. They interpreted the first sharp diffraction peak (FSDP) in the WAXS data as being indicative of correlations between voids in the glass network. This was reflected as a decrease in the FSDP line width. The addition of K_2O resulting in increasing voids with more NBOs formed, expansion of the network structure with larger voids relaxing to smaller ones, resulting in a more ordered overall structure. However, for compositions below 20 mol% K_2O , the first sharp diffraction peak was observed to broaden, and this was interpreted as indicating phase separation.

Olivier *et al.* (2001) compared double quantum (DQ) magic angle spinning NMR (MAS NMR) to MD simulations of binary alkali silicate glasses. They concluded that the Q^4 species were connected to other Q^4 and Q^3 species, thus suggesting that the DQ NMR results support the presence of silica-rich regions, in agreement with the NMR data. Sen and Youngman (2003) investigated the Q^n distribution and connectivity of potassium silicate glasses with silica contents ranging from 76.0 to 97.6 mol%. They concluded that Q^3 species along with two different Q^4 species exist in potassium silicate glasses with >83.5 mol% SiO_2 . And, similar to Olivier *et al.* (2001) the different Q^4 species correspond to Q^4 species connected to one or more Q^3 nearest neighbors and Q^4 species with only Q^4 neighbors, denoted by Q^{4-3} and Q^{4-4} , respectively. Sen and Youngman (2003) also proposed that the random distribution of Q^n species leads to the formation of nanoclusters of Q^3 -rich regions in a Q^4 -rich matrix, with percolating Q^3 -rich clusters forming at 7.5 mol% K_2O composition (see earlier comment on the term “clusters”). However, this is in the phase separated compositional region. More recently, Sawyer *et al.* (2012) showed that the amount of free oxygen in $\text{K}_2\text{O-SiO}_2$ glasses appears to be greater than in equivalent composition $\text{Na}_2\text{O-SiO}_2$ glasses. In addition, Nesbitt *et al.* (2017c) have indicated the potential presence of 3 types of BO with 1, 2 and 3 K cations near or bonded to the BO as observed in the K_2SiO_3 crystal structure. In essence, with increasing K_2O the O coordination potentially increases from 2 $\rightarrow$ 5. Such an increase in BO coordination and its influence on physical properties also remains an area that has not been investigated in any detail.

$\text{Rb}_2\text{O-SiO}_2$ and $\text{Cs}_2\text{O-SiO}_2$ Glasses

There are relative few studies of these glasses. Dupree *et al.* (1986) performed a ^{29}Si and ^{133}Cs MAS NMR study of rubidium and cesium alkali silicate glasses. In comparison to sodium and lithium containing silicate glasses from earlier studies (de Jong *et al.*, 1981; Matson *et al.*, 1983; Schramm *et al.*, 1984) they noted that for low concentrations of rubidium and cesium there is little change in the glass structure and a uniform distribution of Q^3 species and associated cations exist. However, they also observed that at high alkali concentrations (>40 mol%) when there is more than one NBO and cation associated with each silicate tetrahedron, then the Q^n species become more variable resulting in the formation of Q^1 , Q^2 and Q^3 species. Bykov *et al.* (2000) investigated rubidium and cesium silicate glasses using Raman spectroscopy. They found Q^n species distributions consistent with the disproportion reaction Eq. (1) above and the results of Maekawa *et al.* (1991). However, they did note that with increasing alkali size the reaction shifted to the left. Malfait *et al.* (2007a) found that there was an increasing proportion of small rings with increasing alkali size. More recently, O’Shaughnessy *et al.* (2017) investigated $\text{Cs}_2\text{O-SiO}_2$ glass (0–35 mol% Cs_2O) at ambient and high T using Raman spectroscopy and noted that below 10 mol% Cs_2O there was little change in Q^3 , Q^4 and Q^2 concentrations but above 15 mol%, Q^3 increases while Q^4 decreased. The Q^2 concentration showed only a slight increase. At high alkali contents there was a splitting of the fitted high frequency Q^n species bands due to the presence of increasing MBO bonds. Jardón-Álvarez *et al.* (2018) measured a series of cesium-silicate glasses using 2D magic angle flipping (MAF) NMR. They interpreted a decrease in the Q^3 shielding anisotropy with increasing Cs content as a lengthening of the NBO bonds from increasing clustering of the Cs around the NBO. In addition a second Q^3 tetrahedron appeared close to a Cs_2O mole fraction of $x = 0.24$ and was attributed to a finite cluster size with shorter Si-NBO bond lengths.

Mixed Alkali Effect

The mixed alkali effect (MAE) occurs when an additional type of alkali or alkaline-earth cation is added to the binary glass. The mix of two different cations affects a variety of physical properties such as diffusion, electrical conductivity amongst others in a non-linear way (Fig. 4). The explanation for the MAE has revolved around dynamic concepts and two concepts in particular, the transport of

Fig. 4 The non-linear behavior of T_g that occurs when the Na/K ratio is varied in binary alkali-silicate glasses. From Wilkinson, C.J., Potter, A.R., Welch, R.S., *et al.*, 2019. Topological origins of the mixed alkali effect in glass. *J. Phys. Chem. B* 123, 7482–7489.

alkalies through “microdomains” in phase separated glasses or “blocking” of alkali sites as the alkalies migrate in an otherwise homogeneous network (see Henderson, 2005; Wilkinson *et al.*, 2019 and references therein for a summary of the earlier theories).

While the explanation for the MAE remains controversial there does appear to be somewhat of a consensus developing toward a dynamic structure model similar to those of LaCourse (1987), Ingram (1987) and Bunde *et al.* (2004). Currently, the most widely accepted explanation involves cations occupying sites with local structures specific to that cation. Different cations cannot occupy those sites until the vacant site adjusts itself to accommodate the new cation. For example, a vacant Na site has a structural environment suited to the Na^+ cation. When Na^+ moves out of the site the vacant site could accept another Na^+ cation but cannot accept a different cation such as K^+ until the site has adjusted its structural environment to accommodate the much larger K^+ cation. The transport of the different alkalies through the glass will depend on how quickly different sites can adjust to accommodate different cations. Introduction of the new cation also puts additional strain on the glass network due to the different atomic size of the new cation and is well described by a topological modeling approach (Wilkinson *et al.*, 2019). LeLosq *et al.* (2019) have discussed the MAE in aluminosilicate glasses and suggest that while the cation sites are important, the MAE is also related to the degree of heterogeneity of the glasses and the concept of percolation channels.

Albeit less pronounced, the same MAE is found in alkaline-earth silicate glasses where it is called the Mixed Alkaline Earth Effect (MAEE) or more generally the Mixed Modifier Effect (MME). The main reason that MAEE effects are less pronounced than the MAE is that sites must adjust to the 2^+ charge which involves multiple NBO. Very few structural studies have been done on the MAEE in ternary silicate glasses with two AE cations, though the substitution of both Mg by Ca (Calahoo and Zwanziger, 2017; Shan *et al.*, 2017; Zhang *et al.*, 2010), and Mg by Ba (Taniguchi *et al.*, 1997; Lee *et al.*, 2003) has received some attention. When Ba is substituted for Mg in metasilicate glass there is a strong influence on the shielding of the BO and Ba effectively outcompetes Mg for the NBO, leading to significant ordering of the glass (Lee *et al.*, 2003).

The MAEE have been studied in alkali-bearing aluminosilicate glasses in considerable detail (Bäck *et al.*, 2019; Ding *et al.*, 2020; Kjeldsen *et al.*, 2014). The Ding *et al.* (2020) study looked at the inter-play between the Mg for Ca exchange, and three- versus four-fold coordinated B. In fact, ^{14}B is found mainly in end member compositions, rich in either Mg or Ca, whereas ^{13}B and a change in silica connectivity was observed when the concentration of Mg and Ca were roughly equal (Ding *et al.*, 2020). This interplay between the network modifiers and the network formers indicates that, in contrast to pure silicate glasses, the alkaline earth cations may effectively compete for oxygen with weaker network formers (e.g., B, Al). Therefore, the MME may not only be restricted to the modifiers but to chemically complex networks in general. To determine the physical properties of ternary and more complex glasses one should start by consulting Bansal and Doremus (1986) or the SciGlass database (see “Physical Properties section”).

Alkaline-Earth Silicate Glasses

In contrast to the alkali cations, the alkaline-earth (AE) cations have a 2^+ formal charge, a full outer s orbital, and comparable radii. As a result, AE cations bond more readily with multiple oxygens, and therefore are less soluble (Railsback, 2003), and produce more dense silicate glasses and melts (Bottinga and Weill, 1970; Gaskell, 1982). From Be-O to Ba-O the unstrained bond length (r_0) lengthens from 1.38 to 2.29 Å, whereas from Li-O to Cs-O, r_0 changes from 1.46 to 2.42 Å (Brown and Altermatt, 1985; Gagné and Hawthorne, 2016). The interest in the alkaline-earth silicate glasses are three-fold. First, the AE cations, especially Mg and Ca, are ubiquitous in most environments on Earth and from major constituents in seawater, as well as mantle (Railsback, 2003). Second, metallurgical processes often produce refractory glasses, rich in Mg, Ca, Fe, and Si, as a by-product of smelting (e.g., Piatak *et al.*, 2019; Toop and Samis, 1962). Third, AE silicate glasses and glass-ceramics are widely used in industrial applications

Fig. 5 Representative CN_{MO} for MO-SiO₂ glasses where M is Mg (squares), Ca (triangles), Sr (diamonds), Ba (circles). MgO-SiO₂ data comes from ND data of Wilding *et al.*, MS-exp., and molecular dynamics simulations of Al-Hasni and Mountjoy, MS-sim. CMS refers to CaO-MgO-SiO₂ glass results of Cormier and Cuello. CaO-SiO₂ data (CS) comes from MD simulations of Mead and Mountjoy. BaO-SiO₂ data (BS) comes from personal data of Prof. A. Picinin (UFScar). The grand mean CN_{MO} for oxide-based crystals (Gagné and Hawthorne, 2016) for each of the AE have been plotted at 5% and for the pure MO oxides at 100%. such as in solid-oxide fuel cells (Herrmann *et al.*, 2012; Höland and Beall, 2012), and, when doped with rare earth elements these glasses and glass-ceramics are used in LED and re-writable optical storage devices (e.g., Lin *et al.*, 2019; Wang *et al.*, 2013).

The MgO-SiO₂ System

MgO and SiO₂ are major components in the Earth (Bowen and Andersen, 1914) but are also of interest because magnesium substitutes for ferrous iron in many silicate phases due to their similar charge and radius (Brown and Altermatt, 1985). Structural considerations of AE silicate compositions were initially motivated by a desire to explain phase separation and viscous flow (Bockris *et al.*, 1955; Warren, 1942). Early XRD studies on Mg-metasilicate glasses determined a mean Mg-O bond length of 2.14 Å and a magnesium coordination number (CN_{Mg}) of 4.6. These values showed negligible changes for the molten products of these glasses at 1600–1800°C, where the Mg-O bond lengths increased slightly to 2.16 Å (Waseda and Toguri, 1977). In contrast, the Si-O bond length remained constant, at 1.63 Å up to 1800°C. Although the Mg-O bond length remained similar, the CN_{Mg} increased slightly from 3.7 to 3.9 for glassy 44MgO-56SiO₂ at 1790°C (Waseda and Toguri, 1977). For glassy MgSiO₃, bond lengths (and coordination numbers) for Mg-O and Si-O of 2.08 Å (4.1) and 1.63 Å (4.1), respectively, were found (Yin *et al.*, 1983). Small scale molecular dynamics simulations have confirmed this behavior (Matsui, 1996). However, ultimately the significance of non-integer CN_{Mg} , 4.6, raises questions with respect to the coordination distribution and the role Mg plays in the properties in silicate glasses and melts.

Due to the ambiguity of a fractional CN_{Mg} other structural probes and higher resolution studies have been sought to determine the role of Mg, including Mg *K*-edge X-ray absorption near-edge spectroscopy (XANES), Raman, and ²⁵Mg MAS NMR spectroscopies as well as higher resolution diffraction studies (Cormier and Cuello, 2011; Davis *et al.*, 2011; Kalampounias *et al.*, 2009; Kroeker and Stebbins, 2000; Li *et al.*, 1999; Salmon *et al.*, 2019; Sen and Tangeman, 2008; Shimoda *et al.*, 2008; Shimoda and Okuno, 2006; Taniguchi *et al.*, 1997). The majority of these studies essentially agree that the Mg-O bond length in MgSiO₃ glass is close to ~2 Å, with individual values ranging from 1.99 to 2.08 Å and a coordination number (CN_{Mg}) of ~4.5 (ranging from 4.35 to 4.75 depending on the method and constraints used). Most X-ray-based spectroscopic and diffraction studies interpret the CN_{Mg} to represent a mixture of distorted MgO₄ and MgO₅ polyhedra (Wilding *et al.*, 2004a,b). However, several ²⁹Mg MAS NMR studies suggested that the local Mg environment in MgSiO₃ glass is a distorted octahedron (MgO₆) (Kroeker and Stebbins, 2000; Shimoda

Fig. 6 Glass transition temperature, T_g , as a function of AE composition. T_g data of CaO-SiO_2 glasses (filled triangles) are from Kaseman *et al.*, MgO-SiO_2 glasses (squares) are from Wilding *et al.*, $(\text{Ca,Mg})\text{O-SiO}_2$ glasses (empty triangles) from Nasikas, BaO-SiO_2 data (green circles) from personal data of Dr. L. Silva (UFSCar) and come from calorimetry measurements using a heating rate of 10K/min. The data for SrO-SiO_2 (black diamonds) and BaO-SiO_2 (blue circles) come from dilatometry measurements of Shelby (1979). Dotted lines are inferred trends as pure SiO_2 has a T_g around 1190°C. Errors in T_g are generally $\pm 2\text{--}5^\circ\text{C}$ and errors in composition are generally $\pm 0.5\text{ mol}\%$. et al., 2007). If Mg is found in octahedral coordination, it would be the only AE cation that has comparable CN in both crystalline and glassy oxides (Fig. 5). Unlike the other AE cations, the oxygen involved in the Mg polyhedra are mostly NBOs while for the larger cations (e.g., Ca, Ba) bridging oxygens become more important. This is expected to change in more complex compositions (e.g., Lee *et al.*, 2003). The silicon within the MgSiO_3 glass remains in tetrahedral coordination (4.0 ± 0.1) and with only subtle differences reported in the Si-O bond lengths of $1.62 \text{ \AA} \pm 0.01$ (Cormier and Cuello, 2011; Salmon *et al.*, 2019).

The difficulty in determining a mean Mg-O bond length and corresponding CN_{Mg} is due to the overlap and distribution of sites: MgO_4 , MgO_5 , MgO_6 , $\pm\text{MgO}_7$. It is a significant challenge to determine with confidence the CN of any of the alkali or alkaline-earth cations in glasses and melts due to their site distributions. Although clearer in crystalline silicates, this difficulty remains in some situations (e.g., Gagné and Hawthorne, 2016). In early diffraction studies an asymmetric feature in the total structure factors spanning $\sim 1.8\text{--}2.3 \text{ \AA}$ can be modeled using two Mg-O contributions at 1.99 and 2.21 $\text{\AA}$ (Cormier and Cuello, 2011; Wilding *et al.*, 2004a) or a distribution of Mg-O contributions (Cormier and Cuello, 2013). The local environment of Mg in metasilicate glasses has been studied in detail and its behavior at extreme temperatures and pressures has been discussed both experimentally and theoretically (Ghosh *et al.*, 2014; Sakamaki *et al.*, 2014; Salmon *et al.*, 2019; Yi and Lee, 2012). Mg_2SiO_4 glasses and liquids have been studied in detail (Adjaoud *et al.*, 2011; Kohara *et al.*, 2004; De Koker *et al.*, 2008; Sen and Tangeman, 2008; Voronko *et al.*, 2006) as well as invert MgO-SiO_2 glasses where modifier cations are more abundant than silica (Kalampounias *et al.*, 2009; Sen *et al.*, 2009). The CN_{Mg} in glasses may be more rigorously evaluated using simulations. In Mg_2SiO_4 glass, there appears to be roughly 30% MgO_4 , 50% MgO_5 , and 20% MgO_6 (Kohara *et al.*, 2004). The tetrahedral four-fold Mg sites tend to be regular whereas the pentahedral and octahedral sites are rather distorted, as inferred from NMR (Kroeker and Stebbins, 2000). A detailed analysis of Mg in a wide variety of local environments using Mg K-edge XANES may be used as a basis for future studies (Li *et al.*, 1999; Trcera *et al.*, 2009). CN_{Mg} is important as it appears to strongly affect T_g across the $\text{SiO}_2\text{-MgO}$ join, where T_g of invert glasses increases with increasing CN_{Mg} (Wilding *et al.*, 2004a) (Figs. 5 and 6). The results suggest that this is a likely trend for all binary MO-SiO_2 glasses but perhaps not for mixed AE glasses (Fig. 6).

In MgO-SiO_2 glasses, the regions concentrated in Mg are intermixed with the SiO_4 network which is characterized by the network connectivity (Al-Hasni and Mountjoy, 2014; Cormier and Cuello, 2011; Davis *et al.*, 2011; Sen *et al.*, 2009). Ideally, at the orthosilicate composition the connectivity should approach 0, where BO are absent, however, experiments find polymerized Q^n species, $\text{Q} > 0$, which can only exist if O^{2-} is also present in the glass (Sen *et al.*, 2009; Kalampounias *et al.*, 2009; Davis *et al.*, 2011). Simulations indicate the presence of O^{2-} near the metasilicate composition (Al-Hasni and Mountjoy, 2014) whereas experimental evidence from Raman or NMR spectroscopies have suggested O^{2-} is present in suborthosilicate compositions, at

~61% (Kalampounias *et al.*, 2009) and at ~63% (Sen *et al.*, 2009). These results are important for more silica-rich compositions as prior to the last decade structural models of silicate liquids almost ubiquitously assumed that O^{2-} was completely consumed by polymerization reactions and therefore not a significant reactant in these materials (see above).

In comparing the 1D ^{29}Si MAS NMR results to 2D ^{29}Si MAF/MAS NMR studies it is observed that the former systematically overestimate the amount of NBO present. For example, for MgSiO_3 the Q^0 to Q^4 were found to be 1.4%, 19.1%, 53.0%, 25.2%, and 1.4%, respectively, using MAF NMR (Davis *et al.*, 2011) whereas MAS NMR found them to be 0, 25.0, 42.0, 25.7, and 7.3, respectively (Sen *et al.*, 2009). These values are close to a detailed AIM-MD study (Salmon *et al.*, 2019) and contradict several MD studies (Shimoda and Okuno, 2006; Ghosh *et al.*, 2014). Combined, recent NMR, Raman and MD simulations confirm inferences from an early Raman study on a wide range of orthosilicate glasses that O^{2-} is an important oxygen species in silicate melts (Cooney and Sharma, 1990). The relationship between the presence of O^{2-} and the structural, physical and chemical properties of invert glasses remains an area of intensely debated research.

The Ternary MgO-CaO-SiO₂ System

The substitution of Mg by Ca is ubiquitous in AE silicate systems that is important for basic rocks as well as for potential biomedical applications. The diopside composition, $\text{CaMgSi}_2\text{O}_6$, glass has been studied using numerous techniques: ^{25}Mg (George and Stebbins, 1998; Kroeker and Stebbins, 2000; Shimoda *et al.*, 2008), ^{29}Si and ^{17}O NMR (Brandriss and Stebbins, 1988; Nasikas *et al.*, 2012), Ca K-, Mg K-, Si K-, and O K-edge XANES (Binsted *et al.*, 1985; Ildefonse *et al.*, 1995; Li *et al.*, 1999; Moulton *et al.*, 2016b; Trcera *et al.*, 2009), Raman (Franz and Mysen, 1995; Moulton *et al.*, 2016a; Nasikas *et al.*, 2011; Retsinas *et al.*, 2014), X-ray diffraction (XRD) and neutron diffraction (ND) (Cormier and Cuello, 2013; Shimoda *et al.*, 2005; Taniguchi *et al.*, 1997), as well as by theoretical simulations (Sun *et al.*, 2011; Zhang *et al.*, 2010). Finally, Hung *et al.* (2016) provide direct evidence for O^{2-} in near orthosilicate composition (Ca,Mg)-silicate glasses. Other important glasses in this system are found at the compositions of stable mineral phases, åkermanite ($\text{Ca}_2\text{MgSi}_2\text{O}_6$), merwinite ($\text{Ca}_3\text{MgSi}_2\text{O}_8$), and monticellite (CaMgSiO_4), which may serve as entry points into this system.

The CaO-SiO₂ System

The CaO-SiO₂ phase diagram has been re-evaluated by Ottonello *et al.* (2013) whereas the crystal nucleation and growth rates have been studied in detail by Gránásy *et al.* (1998) and Deubener (2005). Early ND, XRD and EXAFS studies focused on the distinctions between the role of Ca and Mg in CaSiO_3 composition glasses (Eckersley *et al.*, 1988; Gaskell *et al.*, 1991; Geere *et al.*, 1983; Mastelaro *et al.*, 2000; Taniguchi *et al.*, 1997; Yin *et al.*, 1986). The EXAFS studies showed an uncanny similarity between the Ca K-edge XANES spectra of $x\text{CaO}-(1-x)\text{SiO}_2$ glasses ($x = 0.32-0.53$) and that of wollastonite (Geere *et al.*, 1983; Gaskell *et al.*, 1991). An ND study refined the local Ca environment to consist of a distribution of Ca-O bond lengths with six near oxygens around 2.24–2.54 Å, and a further oxygen sitting around 2.64 Å, resulting in a total CN_{Ca} of 6.16 ± 0.15 (Eckersley *et al.*, 1988). These results were reinforced by classical molecular dynamics simulation on CaSiO_3 which found a mean Ca-O bond length of 2.48 Å and a CN_{Ca} of 6.3 (Mead and Mountjoy, 2005).

These MD simulations were extended across $x\text{CaO}-(1-x)\text{SiO}_2$ ($x = 0-0.5$) glasses and found that with increasing Ca content there was little change in the Ca-O bond length from 2.37 to 2.42 Å as x changed from 0.1 to 0.5 (Mead and Mountjoy, 2006a). Although the bond length changed by only ~2% the CN_{Ca} increased by 1, from 5.4 to 6.4 across the same interval. The increased CN_{Ca} is due to the additional NBO forming as the CaO content increases. In fact, over the same interval the $\text{CN}_{\text{Ca}}^{\text{BO}}$ decreases from 2.3 to 1.0, whereas $\text{CN}_{\text{Ca}}^{\text{NBO}}$ increases dramatically from 3.1 to 5.4 (Mead and Mountjoy, 2006a,b). These findings of CaSiO_3 glass were supported by a combined ND + RMC study which modeled the distribution of Ca sites between CaO_5 and CaO_7 , and found the a mean CN_{Ca} of 5.83 with $\text{CN}_{\text{Ca}}^{\text{BO}}$ and $\text{CN}_{\text{Ca}}^{\text{NBO}}$ of 0.85 and 4.98, respectively (Cormier and Cuello, 2013). Similarly, ^{43}Ca NMR results found a mean Ca-O bond length of 2.461 and a mean CN_{Ca} of 6.35 (Pedone *et al.*, 2010). Ultimately, in terms of the correlation between CN_{MO} (Fig. 5) and T_g (Fig. 6), these CaO-SiO₂ studies find a comparable trend to MgO-SiO₂ glasses in the invert glass region. These results suggest that regions concentrated in Ca, like regions concentrated in Mg, actually contribute to the network strength of these silicate melts.

All studies on CaO-SiO₂ agree that the SiO₄ connectivity changes gradually across the join (Cormier and Cuello, 2013; Kaseman *et al.*, 2015; Mysen *et al.*, 1982; Neuville, 2006; Pedone *et al.*, 2010; Seo and Tsukihashi, 2004; Tsunawaki *et al.*, 1981; Wu *et al.*, 2004; Zhang *et al.*, 1997). It should be highlighted that, unlike the alkali silicates, NMR studies do not show the systematic trends relating the chemical shielding and quadrupolar parameters to the structural parameters (Pedone *et al.*, 2010). Instead, in order to determine the connectivities in alkaline-earth silicate glasses some constraints or assumptions are required to model the ^{29}Si MAS or MAF NMR spectra. Consequently, earlier ^{29}Si MAS NMR studies using empirical Gaussian fitting were noted to overestimate the Q^2 species by about 15% in CaSiO_3 glass (Charpentier *et al.*, 2013) and only modest correlations between Q^n species and the NMR parameters were found (Pedone *et al.*, 2010). This discrepancy is important because many early Raman studies on connectivity were quantified using empirical corrections based on ^{29}Si MAS NMR results.

CaSiO_3 glass connectivity was studied using ab initio simulations combined with advanced multidimensional NMR methods which found Q^1 - Q^4 of 25.0, 51.7, 18.4 and 5, respectively (Pedone *et al.*, 2010). These results are within error of a 2D ^{29}Si MAS NMR study which found Q^0 - Q^4 of 0.7, 19.3, 54.7, 24.1 and 1.1 (Zhang *et al.*, 1997) and more recent AIM-MD modeling which

found Q^0 - Q^4 of 1, 24, 50, 22, 2, respectively (Salmon *et al.*, 2019). From these models, errors of $\pm 0.5\%$ – 3% depending on the species concentration should be considered an excellent result. Kaseman *et al.* (2015) explored the connectivity of a wide range of CaO-SiO₂ glasses using an empirical Gaussian fitting routine on glasses containing 42%–61% CaO and found CaSiO₃ to have Q^1 - Q^3 of 16.6, 64.0, 19.0 indicating that this model overestimates the amount of Q^2 by $\sim 10\%$. This casts doubt on the absolute values determined across the compositional range but provides a guide to the expected trends. A variety of other studies have investigated the network connectivity of CaO-SiO₂ glasses; however, a comparison of the metasilicate composition alone shows that these studies differ dramatically from the results discussed above (Tsunawaki *et al.*, 1981; Mysen and Frantz, 1993; Franz and Mysen, 1995; Wu *et al.*, 2004; Seo and Tsukihashi, 2004; Mead and Mountjoy, 2005, 2006a).

Network connectivities have been tested by studies which determined the oxygen speciation directly, predominantly from ¹⁷O-based NMR studies (Lee and Stebbins, 2006; Thompson *et al.*, 2012; Kaseman *et al.*, 2015). In general, these studies all indicate that calcium silicate glasses tend to have a mean connectivity within error of their expected values for the reported composition, at least up to 60 mol% CaO (Lee and Stebbins, 2006; Thompson *et al.*, 2012; Kaseman *et al.*, 2015). The ambient condition results above have motivated further studies at gigapascal pressures and high temperatures (Mead and Mountjoy, 2006b; Lee *et al.*, 2014; Neuville *et al.*, 2008; Salmon *et al.*, 2019; Zhang *et al.*, 2010).

Correlations with structure associated with the medium range order have also been investigated in glassy CaSiO₃ (Cormier and Cuello, 2013; Gaskell *et al.*, 1991; Mead and Mountjoy, 2006a,b). In general, as the Ca content increases the number of rings decreases and the proportion of smaller rings decreases (Mead and Mountjoy, 2006a,b). When Mg is substituted for Ca in the metasilicate composition, the smaller Mg cation appears to favor the formation of larger rings (Cormier and Cuello, 2013). Large scale, $> 10,000+$ atoms, glass simulations have further investigated the ring populations (Le Roux and Jund, 2010, 2011) to establish the extent and importance of the medium range structure. We emphasize that chain-like and sheet-like structures, akin to those found in the crystalline phases, have not been found in simulations nor in critical analysis of diffraction features (Mead and Mountjoy, 2005; Cormier and Cuello, 2013) as reported frequently in studies prior to the year 2000. The same was concluded for the BaO-SiO₂ system (Rai and Mountjoy, 2014). In conclusion, alkaline-earth silicate glasses do not contain chain or sheet structures.

Beryllium Silicate Glasses

These glasses have been very rarely studied. This is partially due to the toxicity and carcinogenic nature of BeO. Unlike the other alkaline-earth cations, Be appears to be only found in four-fold coordination and due to its high field strength is considered a network former (Sen and Yu, 2005). The Be-rich melts and the crystalline phase beryl, Be₃Al₂(Si₆O₁₈), have received considerably more attention due to its gem variety, emerald (Riebling and Duke, 1967). Further information can be found on the effects of Be on viscosity (Hess *et al.*, 1996) or on its structural behavior in alkali silicate glasses (Clare *et al.*, 1997; Wójcik *et al.*, 2019).

Strontium Silicate Glasses

Strontium silicate glasses are not common although the effect of Sr on the viscosity for various silicate and aluminosilicate melts are known (Richet and Bottinga, 1986) and the SrO-SiO₂ phase diagram has been re-evaluated (Shukla *et al.*, 2017 and references therein). The properties may be found in: Bansal and Doremus (1986); Iwamoto *et al.* (1984); and Shelby (1979). Sr metasilicate glass has been studied using ND (Cormier *et al.*, 1999) and SrO-2.36SiO₂ glass was investigated by 2D ²⁹Si MAF NMR (Baltisberger *et al.*, 2016); however, neither study came to a conclusion regarding the glass structure. Similar to beryllium, the structure and properties of Sr-bearing aluminosilicate glasses have been more commonly investigated (Novikov *et al.*, 2017; Weigel *et al.*, 2016). The local Sr environment has been investigated in a wide variety of mixed alkali/alkaline-earth aluminoborosilicate nuclear waste glasses using Sr K-edge XANES/EXAFS (McKeown *et al.*, 2003).

The BaO-SiO₂ System

Within this binary the BaSi₂O₅ composition is most studied due to its volume nucleating ability (Fokin *et al.*, 2016; Moulton *et al.*, 2018, 2019; Ramsden and James, 1984; Takahashi *et al.*, 2009a,b; Zanutto and James, 1988) and interesting decoupling behavior just above T_g (Rodrigues *et al.*, 2018). Of the binary alkali or AE-silicate systems, BaO-SiO₂ has the most stable phases at ambient conditions making the structural aspects of this system quite complex. At least nine phases are currently known (Gorelova *et al.*, 2016; Grebenshchikov and Toropov, 1962) and several more are known to contain six-fold silicon at high-pressure (Hazen *et al.*, 1999; Yusa *et al.*, 2007). The phase diagram of the BaO-SiO₂ system has recently been re-evaluated (Oehlschlegel, 1975; Shukla *et al.*, 2018).

An early XRD and ND study on BaSi₂O₅ glass showed sharp peaks associated with the Si-O bonds at 1.60 Å and a broad second peak at 2.76 Å (XRD) or 2.63 Å (ND) which were assigned to the Ba-O and O-O distances, respectively (Hasegawa and Yasui, 1987). Beyond the first coordination sphere, a series of peaks at 3.60, 4.15, and 4.94 Å were interpreted loosely in terms of sheet structures (see comments at the end of the CaO-SiO₂ section) found in sanbornite (Hasegawa and Yasui, 1987). Another study on both crystal and glassy Ba₄Si₆O₁₆ highlighted features in the structure factor of the glass at 1.1 Å⁻¹ and crystal at 1.07 Å⁻¹ indicating some similarity related to the Ba cation distribution (Cormier *et al.*, 1999). Schlenz *et al.* (2002) found an Si-O bond length of 1.62 Å in

Fig. 7 The Ba-O-Ba connectivity distribution as a function of composition. Reproduced with permission from Rai, M., Mountjoy, G., 2014. Molecular dynamics modelling of the structure of barium silicate glasses BaO-SiO₂. *J. Non-Cryst. Solids* 401, 159–163.

BaSi₂O₅ glass using multiple techniques; however, problems with overlapping features of Ba-O and Si-Si between 2.66 and 2.96 Å precluded clear interpretations. A systematic Si *K*-edge XANES study on crystals and glasses found a monotonic edge shift in the crystalline phases whereas glass of 33.3BaO · 66.6SiO₂ and 37BaO · 63SiO₂ showed a similar response to sanbornite indicating a predominantly Q³-based glass (Bender *et al.*, 2002). These studies have built on a variety of investigations contrasting the crystalline phases against the glasses using Raman (Etchepare, 1970; Franz and Mysen, 1995; Mysen and Frantz, 1993; Takahashi *et al.*, 2009a), ²⁹Si NMR (Schneider *et al.*, 2003) and ¹⁷O NMR (Thompson *et al.*, 2012), Si *K*-edge XANES, XPS (Bender *et al.*, 2002; Schlenz *et al.*, 2002), MD and reverse Monte Carlo (RMC) simulations (Rai and Mountjoy, 2014; Schlenz *et al.*, 2002).

Clarity on the structure of glasses in the BaO-SiO₂ system mainly come from the MD simulations of Rai and Mountjoy (2014) covering the compositions *x*BaO-(1-*x*)SiO₂ (*x* = 0.25, 0.333, 0.4 and 0.5). They found an invariant Si-O bond length of 1.59 Å between 25BaO · 75SiO₂ and 50BaO · 50SiO₂ (Rai and Mountjoy, 2014). A Ba-O bond length of 2.79 Å was found for the nearest neighbor oxygen atoms which is comparable to the 2.76 Å found previously (Hasegawa and Yasui, 1987). The Qⁿ distribution for BaSi₂O₅ of Q¹⁻⁴ was found to be 4.2, 20.4, 43.6, 31.1 (Rai and Mountjoy, 2014), respectively, which is in line with previous MD results which found Q⁰⁻⁴ to be 1, 7, 28.9, 45.2, 17.9 (Schlenz *et al.*, 2002). However, these Qⁿ distributions are considerably broader than experimentally determined Q²⁻⁴ contents found to be 24, 62, and 14, respectively (Schneider *et al.*, 2003). The connectivity of Ba-silicate glasses in the phase separation region at BaO contents of 26.7% and 27.5% found Q³ and Q⁴ proportions of 72.8% and 27.2% and 75.7% and 24.3%, respectively (Baltisberger *et al.*, 2016). These results differ strongly from the MD simulations of the 25 mol% BaO silicate glass which found Q¹⁻⁴ contents of 1.1, 11, 42, and 45.8, respectively (Rai and Mountjoy, 2014), indicating that the former glasses likely suffered phase separation.

The local Ba environment was also investigated by Rai and Mountjoy (2014). The Ba-O distribution shows no absolute minimum between the first and second spheres and therefore, CN_{Ba} was determined using a cutoff of 3.3 Å. CN_{Ba} was found to increase from 6.5 to 6.8 for BaO compositions from 25 to 33 mol% (Rai and Mountjoy, 2014). CN_{Ba} appears to remain constant at 6.8 ± 0.1 up to 50 mol% BaO (Rai and Mountjoy, 2014). This negligible change in CN_{Ba} (Fig. 5) contrasts with CN_{Ca} which showed a monotonic increase, albeit at much higher MO contents (Cormier and Cuello, 2013) and appears to indicate that the large size of the Ba cations imposes a steric limit to its coordination. In fact, for all compositions from 25 to 50 mol% BaO, the Ba-O-Ba connectivity (Fig. 7) was found as continuous channels throughout the network with no indication of phase separation or cluster formation (Rai and Mountjoy, 2014). The role of Ba in the silicate-based glasses remains poorly constrained, especially in relation to MAE effects.

There are many studies of how the AE cations substitute into silicate-based glasses. These studies primarily focus on the MME (Na, K, Ca, Ba – Bäck *et al.*, 2019; Na-Ca-Ba – Lee *et al.*, 2003; Na-Mg – Trcera *et al.*, 2009, 2011a,b; K-Ca-Cs – Zhang *et al.*, 2014) and on substitution of Si for other network formers such as B, Al, Ge, Ti (Ali and Jonson, 2011; Angeli *et al.*, 2012; Majérus *et al.*, 2004; Möncke *et al.*, 2009; Neuville *et al.*, 2008, 2010).

Physical Properties

The common physical properties of binary silicate glasses have a long history that was largely established by the end of the last century. For a concise and cogent overview of essential properties (e.g., density, heat capacity, refractive index, durability,

toughness, strength, etc.) the Handbook of Glass Properties by [Bansal and Doremus \(1986\)](#) is excellent. The seminal works of Bockris, Bottinga, Richet and colleagues should be consulted ([Bockris *et al.*, 1955](#); [Tomlinson *et al.*, 1958](#); [Bottinga and Weill, 1970](#)). For an updated view the reader should consult glass science textbooks: [Shelby \(2005\)](#); [Mauro and Varshneya \(2019\)](#); [Mysen and Richet \(2019\)](#). A list of international databases can be found in the “Relevant Websites section”. Historically, the most important property database has been the SciGlass database which currently consists of 420,000 glass entries, of a wide range of compositions and their properties. The SciGlass database was initiated as the Handbook of Glass Data by [Mazurin *et al.* \(1983\)](#) and is now freely downloadable (see “Relevant Websites section”).

Applications

Silicate-based glasses and glass-ceramics have three main facets that make them advantageous over many other materials: (1) their compositional and corresponding property ranges; (2) their ability to crystallize (e.g., the formation of micro-textured glass-ceramics); (3) the ability to add small amounts of dopants (e.g., 0.5 wt% TiO_2) to the starting composition that may add new properties (e.g., optical, magnetic) in phenomenal fashion. Varying the composition, microtexture and dopants allows manufacturers to adjust the thermal, chemical, mechanical, optical, biological, electrical and magnetic properties to tailor glasses and glass-ceramics for application in essentially every major industry. In many cases there is no material available other than glasses and glass-ceramics, that can be formed and temporarily deformed without forming pores, defects or being permanently damaged.

The discussion below is meant to highlight entry points into the vast literature on applications. For an introduction to binary and more complex silicate-based glasses, glass-ceramics and their applications the reader is referred to the influential work of [Stookey \(1959\)](#) and [Gaskell \(1997\)](#), as well as the volumes by [Lewis \(1989\)](#), [Shelby \(2005\)](#), [Höland and Beall \(2012\)](#), [Mauro and Varshneya \(2019\)](#) or [Goldstein *et al.* \(2020\)](#). The trade-names and compositions of the most important silicate-based commercial glasses can be found in the latter four books.

The important industrial applications can be broadly divided into four categories: materials for building and construction (e.g., cement, tiles, glazes), mechanical applications (e.g., solid oxide fuel cell sealants, armor), medical applications (e.g., implants, dental) and optical-electrical or magnetic devices (e.g., light emitting diode materials, memory devices, lasers). There are few direct applications of simple binary alkali- or alkaline-earth silicate glasses. However, $\text{Li}_2\text{O}-2\text{SiO}_2$ and $\text{BaO}-2\text{SiO}_2$ (see above) have long been important due to the dopants known to enhance their properties. In addition, SiO_2 -rich glasses and the $\text{MgO}-\text{SiO}_2$, $\text{CaO}-\text{SiO}_2$ and $\text{Na}_2\text{O}-\text{CaO}-\text{SiO}_2$ systems have been widely used in industry, especially where they have been mixed with Al_2O_3 . This should make obvious the importance of phase separation as it is common in silica-rich glass compositions whereas the MME phenomenon is fundamental in soda-lime-based silicate glasses which constitute the majority of industrial glass production.

The $\text{CaO}-\text{SiO}_2$ system is among the most important industrial systems because of its relevance to cement production where Ca_3SiO_5 and Ca_2SiO_4 and their hydrous and amorphous by-products are crucial components ([Adu-Amankwah *et al.*, 2017](#); [Pioro and Pioro, 2004](#)). Silicate-based mixtures where various combinations of CaO , MgO , Al_2O_3 , B_2O_3 , K_2O , ZnO , Fe_2O_3 , Li_2O , and TiO_2 are found, form the base ingredients of the most common ceramic tiles and glazes used worldwide for over three millennia ([Casasola *et al.*, 2012](#)). The Ca_3SiO_5 and Ca_2SiO_4 phases have been used in dental applications as a standard material for pulp capping due to their antimicrobial attributes and ability to bind with dentine ([Choi *et al.*, 2019](#)). However, more commonly Li_2O -based silicate glasses and glass-ceramics are used due to their favorable translucency (capable of producing a tooth-like appearance), strength, fracture toughness, machinability and chemical durability ([Montazerian and Zanotto, 2017](#)).

Bio-active glasses have a more recent history and are based on mixtures rich in SiO_2 , Na_2O , CaO and P_2O_5 with varying minor components in order to produce durable, chemically and biologically inert glass-ceramics that will bind to bone as implants ([Crovace *et al.*, 2016](#)). These bioglasses have seen intense interest especially in the last decade in medical applications as they can be designed as long lasting or temporary implants that dissolve as the healing process takes place (e.g., [Rahaman *et al.*, 2011](#); [Zheng *et al.*, 2019](#)). In nature, radiolarians draw silica from seawater to form intricate scaffold designs. This means that manipulation of silica-based materials is possible at low temperature. The possibility of low temperature applications has led several groups to pursue these reactions as an alternative synthesis pathway ([Gordon *et al.*, 2009](#)).

Low concentration dopants have at least two crucial effects on glass: (1) to permit volume nucleation, and (2) to promote optical or magnetic properties. Volume nucleation is essential to produce homogeneous crystallization throughout the glass so that properties may be consistent and reliable. An intergrown distribution of acicular crystals is highly desirable to deflect and distribute stresses so that the fracture toughness of glass-ceramics is increased. Combinations of rare-earth element and transition metal dopants in silicate-based glasses have been extensively investigated for use as fiber optic lasers ([Dragic *et al.*, 2018](#)), in optical storage devices ([Lin *et al.*, 2019](#)), in light emitting diode and luminescence materials ([Liu *et al.*, 2018](#)), and as transparent windows, especially for infrared and microwave applications ([Xiao *et al.*, 2020](#)). Finally, ion-exchange glasses and glass-ceramics are produced where a small alkali, such as Li_2O or Na_2O , is substituted for a large one in $\text{M}_2\text{O}-\text{Al}_2\text{O}_3-\text{SiO}_2$ -based glasses ([Beall *et al.*, 2016](#)). Ion-exchange glasses have been used in billions of smartphones in the last decade. When large alkalis are inserted into the glass network, compressive stresses are formed that result in a tougher and stronger glass. More recently, ion exchange glass-ceramics are being pursued as the ion exchange process can induce favorable amorphization and phase changes which open new possible applications beyond that of the original glass ([Beall *et al.*, 2016](#)).

Concluding Remarks

Alkali and alkaline-earth silicate glasses are among the most studied glasses on the earth due to their important chemical and physical properties which make these systems relevant to both volcanology and petrology as well as glass and materials science. At high silica contents, phase separation is an important process that is used to produce low thermal expansion cookware among many other products. More generally, phase separation is a fundamental process that occurs in magmas and results in some of the largest ore deposits on Earth. When mixed together, the mixed alkali effect induces non-linear behavior in the properties that are important for increasing the strength and durability of the glasses. Though much less work has been done on alkaline-earth silicate glasses, they exhibit all of the features found in alkali silicate glasses. The alkali- and alkaline-earth-bearing silicate glasses remain the templates used to understand more complex silicate glasses, to understand the magmatic evolution of Earth and beyond, and to understand the glass-ceramics used every day of our lives.

Soda-Lime-Silica Glasses

Russell J Hand, University of Sheffield, Sheffield, United Kingdom

© 2021 Elsevier Inc. All rights reserved.

Introduction

When the average person uses the term glass they are probably referring to soda-lime-silica (SLS) glass, even if they do not realize that this is the case, as most bulk glass i.e., container glass (bottles; ~45%–50% of the global glass market by weight), flat glass (windows etc.; ~30% of the global glass market by weight), and glassware (drinking glasses) are SLS glasses. The widespread use of SLS glasses is due to the availability of suitable raw materials and automated processes that have been developed around the viscosity-temperature behavior of these compositions. It also reflects the fact that SLS glasses can be produced to suitable optical standard for applications such as windscreens, and have sufficient chemical durability for use in a range of applications.

SLS glasses are readily produced by the melt-quench route wherein a batch of raw materials are heated and react together to form a melt which then forms a glass on cooling. When a glass forming melt such as a soda-lime-silica melt is cooled, rather than undergoing a liquid-solid phase change at, or just below, the temperature, T_m , and crystallizing (T_m being the melting point of the crystals) there is a continuous change from the liquid to a solid through the glass transformation range (see Fig. 1). Hence on cooling an SLS melt first becomes a supercooled liquid then, as it passes through the glass transformation range, it can be viewed as a visco-elastic liquid followed by a visco-elastic solid, before finally becoming a brittle solid. Although the glass transformation (or transition) occurs continuously over a range of temperatures as shown in Fig. 1, for convenience it is often characterized by a single temperature known as the glass transition temperature, T_g , which can be measured using either thermal analysis or dilatometry. For SLS glasses T_g will typically be in the range 530–580°C, although the precise value depends on the specific glass composition and thermal history.

Glasses are therefore not equilibrium phases and eventually on very long timescales all glasses are expected to crystallize (Zanotto and Mauro, 2017). However, for all practical purposes, readily formed glasses such as SLS glasses are stable materials that will remain in the glassy state on at least millennium timescales, as shown by the existence of SLS glasses dating back to ancient Egyptian and Roman times.

Compositions

All glasses have non-crystalline or amorphous atomic structures that are similar to those of the melts from which they are formed. As a result, while they have short range order at the atomic scale they do not exhibit any long range order; the presence of medium range order remains a subject for debate. Hence glasses also do not have fixed chemical compositions (unless they are single component) and for any given glass type a range of chemical compositions is possible. The soda-lime-silica system is no exception and there is a large glass forming region in the soda-lime-silica (SLS) ternary system (see Fig. 2(a)).

Soda-lime-silica ($\text{Na}_2\text{O}-\text{CaO}-\text{SiO}_2$) glasses are network oxide glasses primarily based on the oxides of sodium, calcium and silica. It is important to note that these oxides are not individually present in the final glass and thus a glass composition

Fig. 1 Volume versus temperature diagram showing the glass transformation as compared to a liquid-solid phase change.

Fig. 2 (a) Na_2O - CaO - SiO_2 ternary diagram (mol%) showing the glass forming region (gray region) and average, reduced, compositions for some ancient/historic (open symbols) and modern SLS glasses (filled symbols); (b) enlargement of the silica rich corner of the Na_2O - CaO - SiO_2 equilibrium phase diagram with the same glass compositions superimposed on it. Compositional reduction based on considering all alkali oxides as Na_2O (corrected for Al_2O_3 charge balance), all alkaline earth oxides as CaO and charge balanced Al_2O_3 as SiO_2 . $x\text{Na}_2\text{O}\cdot y\text{CaO}\cdot z\text{SiO}_2$ is arguably more correctly written as $\text{Na}_{2x}\text{Ca}_y\text{Si}_z\text{O}_{x+y+2z}$, although the compositions are generally reported in oxide terms for convenience. Small amounts of other oxides will also be present in commercial SLS compositions, in most cases due to their effects on processing and/or on the final glass properties. Specifically most commercial SLS glasses will contain at least small amounts of potassia (K_2O), magnesia (MgO) and alumina (Al_2O_3) and thus they could be considered as part of the Na_2O - K_2O - MgO - CaO - Al_2O_3 - SiO_2 glass system. The presence of these other oxides can be expected to result in shifts of the phase boundaries shown in Fig. 2(a) and (b).

Silica (SiO_2) is the network former and is capable of forming a glass on its own. The structure of pure silica glass is a fully connected three dimensional network of corner linked SiO_4 tetrahedra (see Fig. 3(a)), with each Si–O bond having primarily covalent character. However pure silica is difficult to melt on its own as it requires temperatures in excess of 1720°C . In comparison soda-lime-silica glasses that contain the network modifiers soda (Na_2O) and lime (CaO), which depolymerize the network (see Fig. 3(b)), can be produced using less extreme temperatures. In this case the backbone of the glass structure still consists of corner linked SiO_4 tetrahedra, but some of the corner oxygens are now bonded to either a sodium ion or a calcium ion rather than to another silicon. Oxygens that participate in Si–O–Si bonds are known as bridging oxygens (BOs), whereas those that participate in Si–O–Na or Si–O–Ca bonds are known as non-bridging oxygens (NBOs). A single sodium leads to the formation of one NBO and a calcium leads to the formation of two NBOs, with the Na–O and Ca–O bonds both being primarily ionic in character. The depolymerization of the network through the addition of network modifiers significantly reduces the melt viscosity at any given temperature thus enabling SLS glass production at commercially viable temperatures. Although a reduction in melt viscosity at any particular temperature could be achieved just through the addition of soda to silica this results in non-durable “water” glasses, due to the relatively high mobility of sodium ions in the glass structure. Calcium ions occupy similar sites to the sodium ones due to their similar size, impeding the motion of the latter and thus resulting in a sufficiently durable glass that it can be successfully used for the long-term storage of liquids (containers or bottles) as well as exterior windows. A lack of lime arising from improved purification techniques being applied to ashes used as a soda source means that historic Venetian cristallo glasses (see Fig. 2(a) and Table 1) have poor chemical durability, with the result that many examples in museum collections are now suffering from significant degradation.

SLS glass production has a long history with some of the earliest manmade glasses being SLS compositions, with both the ancient Egyptians (~ 1500 BCE) and the Romans producing SLS glass composition. The ancient Egyptian SLS glasses had relatively low silica contents (see Fig. 2(a) and Table 1) compared to subsequent SLS compositions. Since Roman times the molar silica content has varied relatively little although there have been larger variations in the soda and lime contents. In particular, in medieval times in northern Europe where forest plants were as the alkali source, rather than either natron or marine plants

Fig. 3 Schematic diagrams of (a) a pure silica network consisting of corner connected SiO_4 tetrahedra and (b) a soda-lime-silica glass showing one Na^+ ion (pale brown) bonded to a non-bridging oxygen (NBO) and one Ca^{2+} ion (lime green) bonded to 2 NBOs: Si atoms are dark red, bridging oxygens are black, the NBO is gray, solid lines indicate bonds; dashed lines delimit the SiO_4 tetrahedra.

Table 1 Major components of SLS glasses expressed as moles oxide per mole of SiO_2

(barilla), the resultant glass compositions contain large amounts of potassia and have low soda contents and are often therefore considered as potassia-lime-silica glasses rather than soda-lime-silica glasses. In the 19th and 20th centuries there was some limited evolution of composition over time in response to production requirements (Smrček, 2010). However modern compositions tend vary relatively little between manufacturers although there are some differences between container glass and float glass (see Table 2). In particular, the increased use of recycled glass as a batch material in container manufacture is now promoting a tendency towards a common composition.

Typical modern SLS compositions contain ~13–14 mol% Na_2O , ~9–10 mol% CaO and ~72 mol% SiO_2 . The compositions include deliberate additions of alumina to both improve durability and suppress crystallization. The alumina forms AlO_4^- tetrahedra with charge balance being provided by Na^+ ions, which are therefore no longer bonded via an NBO to a silicon. The AlO_4^- tetrahedra form part of the network and thus alumina additions lead to a reduction in NBOs and an increase in network connectivity increasing both viscosity at a given temperature and chemical durability. Magnesia (MgO) is also deliberately added to modern SLS compositions to reduce the liquidus temperature (the temperature at which the last crystal phase would melt on heating) and, like alumina, to suppress the tendency to crystallization, with float (flat) glass having a higher magnesia content than container glass. Some iron will also be present in commercial SLS glasses; the level being dependent on application and allowable cost.

The presence of the additional components in the glass means that the crystalline phase boundaries shown in Fig. 2(b) will be shifted from those shown which are for the three component SLS system. In practice container glass compositions tend to fall in the primary devitrite ($1:3:6$ or $\text{Na}_2\text{O} \cdot 3\text{CaO} \cdot 6\text{SiO}_2$) phase field whereas float glass is close to the silica-devitrite-wollastonite ($\text{CaO} \cdot \text{SiO}_2$) phase boundary, with liquidus temperatures (T_L) typically being in the range of 990–1050°C depending on composition.

Table 2 Compositions of typical high volume commercial SLS glasses (wt%). Container refers to bottles which may be clear, amber or green; float to flat glass; glassware to drinking glasses and A-glass to insulation fibers

Oxide	Container	Float	Glassware	A-glass
Na ₂ O	12–15	12–14	12–14	12–15
CaO	10–12	7–10	7–9	9–11
SiO ₂	70–73	70–74	70–74	71–73
K ₂ O	0–1	0–0.5	0–2.5	0–1.5
MgO	0.5–2	2–4	1–2	1–4
Al ₂ O ₃	1–2	0–1	1–2	0.5–2.5
Fe ₂ O ₃	0–1	0–1	0–0.05	0–0.5
Cr ₂ O ₃	0–0.3	0–0.3	0	0
TiO ₂	0–0.1	0–0.1	0–0.05	0–0.1
B ₂ O ₃	0	0	0	0–0.5
SO ₃	0–0.5	0–0.5	0–0.5	0–0.5

Bioactive glasses, such as 45S5, can also be considered as modified SLS glasses albeit with low silica contents compared to conventional SLS glasses (see Fig. 2(a)) and the addition of a second glass former, P₂O₅. In this case the low silica content combined with high soda and lime contents results in a glass where its solubility in the human body results in beneficial bioactive behavior.

SLS Glass Structure

It is conventional to describe the connectivity of silicate glasses in terms of Q species. The Q species refer to the number of bridging oxygens that participate in Si–O–Si bonds on a given silica tetrahedron. Thus pure silica, which is fully connected, has just Q⁴ tetrahedra. Tetrahedra with one NBO are referred to as Q³, those with two NBOs as Q², three NBOs as Q¹ and isolated tetrahedra with all NBOs as Q⁰. Adding network modifiers, such as Na₂O and CaO will lead to an increase in the number of Qⁿ⁻¹ species at the expense of Qⁿ species. Typical SLS glass compositions contain a mixture of primarily Q³ tetrahedra with some Q⁴ tetrahedra. Although depolymerization largely happens sequentially with Q⁴ units being first converted to Q³ units and only once this is complete are Q³ units converted to Q² units, in practice some Q² tetrahedra are also likely to be present due to disproportionation whereby Q³ ⇌ Q⁴ + Q² also occurs. The amounts of the different Qⁿ species can be measured using nuclear magnetic resonance (NMR).

Although as network modifiers, Na⁺ and Ca²⁺ ions, formally lead to the production of one or two NBOs respectively, in practice these species will be surrounded by both BOs and NBOs from adjacent tetrahedral units with Na having an oxygen coordination of ~6 in alumina free SLS compositions and ~6–8 if alumina is present. Meanwhile Ca has an oxygen coordination of ~4–5 in alumina free compositions (Le Losq *et al.*, 2019). As the amount of alumina in commercial SLS glasses is relatively low all of the alumina can be charge compensated by sodium ions hence such glasses will contain both SiO₄ tetrahedra and a small number of AlO₄ tetrahedra.

Many textbooks still refer to the Zachariasen-Warren continuous random network (CRN) model for glass structure in which the modifiers are essentially randomly distributed. However various lines of evidence indicate that there is, in fact, some clustering of the modifiers through the glass network with the modified random network (MRN) model of Greaves *et al.* (1981) having silica rich regions separated by percolating channels of modifier ions (see Fig. 4). Although Fig. 4 is a schematic of a soda-silica glass only, the improvement in chemical durability seen when lime replaces some of the soda to produce SLS glasses implies that the calcium ions would be located in the same channels as the sodium ions.

Commercial Production of SLS Glasses

Both container and flat glass are made on the large scale with typical container furnaces producing 300 tonnes per day (tpd) of glass. Float furnaces for flat glass are uneconomic below 300 tpd and the largest modern glass plants now can produce 1000 tpd.

Primary raw materials for commercial SLS glass production are a low iron glass making sand (usually > 99 wt% SiO₂), soda ash (Na₂CO₃) which supplies soda (Na₂O), and limestone (CaCO₃) which supplies lime (CaO). Soda ash may be from a mineral source, namely trona Na₃H(CO₃)₂ · 2(H₂O), or is an industrial chemical produced by the Solvay or ammonia-soda process. Industrially produced soda ash is responsible for a significant fraction of the embodied energy of commercial SLS glass and thus there has been increasing interest in mineral sources in recent years. Some soda may also be supplied by sodium sulfate (salt cake) added to aid bubble removal from the melt (fining) and from the alumina sources. The use of sulfate (or sulfide) during manufacture leads to a residual sulfur content in most SLS glasses with contents ranging from ~0.2 wt% SO₃ (equivalent) in colorless glass to ~0.05 wt% SO₃ (equivalent) in amber glass with the S being present in a range of oxidation states (Bingham *et al.*, 2010). As most commercial SLS glasses also contain magnesia (MgO) some lime is also usually supplied by dolomite (xMgCO₃ · (1 – x)CaCO₃; while in the ideal case x = 0.5 in practice it varies with dolomite source). Alumina is supplied by alkali

Fig. 4 Schematic 2D diagram of the modified random network model of Greaves *et al.* showing percolating sodium channels separating silica rich regions in a soda-silica glass, with the silica units being represented as trigonal rather than tetrahedral to enable a 2D representation. Based on Greaves, G.N., Fontaine, A., Lagarde, P., Raoux, D., Gurman, S.J., 1981. Local structure of silicate glasses. *Nature* 293, 611–616. Hand, R.J., Seddon, A.B., 1997. An hypothesis on the nature of Griffith's cracks in alkali silicate and silica glasses. *Physics and Chemistry of Glasses* 38, 11–14.

aluminosilicate minerals, such as feldspars or nepheline syenite, which typically also supply some soda, potassia (K_2O) and silica. Any potassia in the final composition is usually a consequence of the alumina source used. Small amounts (typically < 1 wt%) of coloring elements may also be present. Notably iron may be present due to impurities in the raw materials (especially the sand), although it can also be introduced deliberately.

Cullet (recycled glass) will also be used in the glass batch; the use of well controlled in-house cullet from rejected product has long been a feature of commercial glass production, but nowadays significant quantities of cullet come from external sources. In container melting (especially for green glass where impurity levels are less of a concern) over 80% of the glass batch may be cullet but the higher optical requirements in flat glass applications limits the amount of cullet used in float furnaces. Externally sourced cullet can impact the redox conditions in the furnace if it contains relatively large amounts of organic contamination.

While the use of cullet reduces the production energy demand, SLS glass production remains an energy intensive process. It is therefore desirable to develop SLS compositions that can be produced at lower temperatures. This is far from straightforward as a range of often competing factors have to be taken into account. For example, increasing the soda content with respect to the other components would reduce the required melting temperature; however such a change would reduce the chemical durability of the product. The potential for reformulating SLS glass compositions has been reviewed in detail by Bingham (2010) and to be commercially viable any reformulation has to balance a range of production and cost requirements. SLS glass products are commodity items and thus there is a strong downward pressure on costs. Furthermore, the large daily production volumes (300–1000 tpd) mean that companies can be reluctant to implement even small changes.

Compositional changes could also, in principle, be made to alter the properties of the final glass. However, such changes are potentially expensive and could negatively affect processing conditions. Thus, a more common approach is to add value by applying surface coatings using techniques such as chemical and physical vapor deposition (CVD and PVD respectively).

Commercial SLS glass melting furnaces are generally fossil fuel fired using natural gas, oxy-fuel mixtures or oil firing. The burners are positioned above the melt and thus the transfer of heat through the melt by both conduction and radiation is important in the melting process. The use of recuperators or regenerators (larger furnaces) to recover heat from the exhaust gases is essential in maximizing fuel efficiency. As SLS melts are sufficiently conducting, electric boost is used in some glass tanks to provide additional

Fig. 5 Viscosity as a function of temperature for pure silica and two SLS compositions (DGG standard glass I and 21Na₂O-9CaO-70SiO₂ (wt%)). Data from Doremus, R.H., 2002. Viscosity of silica. *Journal of Applied Physics* 92, 7619–7629. Note viscosity here is given in Pa s whereas the glass industry commonly uses dPa s.

Joule heating to increase melting rate and pull (glass production) rate. The possibility of utilizing Joule heating means that in principle large scale SLS glass manufacture could be undertaken using all electric melters, and could allow the industry to move away from fossil fuels. However, to be commercially viable for commodity products such as SLS containers and flat glass, this requires a significant reduction in the cost of electricity. To be effective it also requires the electricity supply to be decarbonized.

Viscosity-Temperature Behavior and SLS Glass Production

For network glasses such as SLS glasses melt viscosity is a strong function of temperature (see Fig. 5). This has an impact on glass processing with various viscosity levels being defined based on practical performance.

During glass melting the emphasis is on melting all of the raw materials and homogenizing the resultant melt, together with removal of bubbles from the melt. These processes are generally quicker at high temperatures and lower viscosities, with the melt viscosity typically being ~ 1 Pa s. Even so commercial furnace residence times can be up to 36 h to ensure good quality output. For forming higher viscosities are required and thus glass forming necessarily takes place at lower temperatures than the initial melting stage. The working point (10^3 Pa s) and the softening point ($10^{6.65}$ Pa s) correspond to the highest and lowest temperatures respectively at which a melt can be formed to shape, although this can be further restricted by crystallization. To avoid problems with crystallization the working point (T_W) should be above the liquidus temperature (T_L). For container manufacturing the difference $T_W - T_L$ should be at least 10–20°C. The annealing point (10^{12} Pa s) and the strain point ($10^{13.5}$ Pa s) define the temperature boundaries of the glass transformation range and its importance in annealing; the former temperature is often taken as being the glass transition temperature. For commercial SLS production the melting temperature is typically $\sim 1500^\circ\text{C}$, the forming temperature $\sim 1200^\circ\text{C}$ and the annealing temperature $\sim 550^\circ\text{C}$.

As knowledge of viscosity-temperature (η - T) behavior is essential for good control of commercial glass production a number of equations have been developed to describe this behavior. Of these the Vogel-Fulcher-Tammann (VFT) equation:

$$\log \eta = A + \frac{B}{T - T_0} \quad (1)$$

where A , B and T_0 are constants, is probably best known and is widely used in the glass industry as it provides a good description of the viscosity of glass melts in the temperature range of commercial interest. Lakatos *et al.* (1972, 1976) have published empirical models enabling the parameters A , B and T_0 in the VFT equation to be determined from the composition for a range of glass compositions (see Table 3). More recently Fluegel (2007) has developed a more sophisticated, albeit still empirical, set of calculations for a wide range of glass compositions to determine the parameters in the VFT equation from the composition. This model has been implemented as an Excel spreadsheet downloadable from the web (see “Relevant Website section”), which also produces the viscosity-temperature curve. It should be noted that in the Lakatos fits for the VFT equation, η is measured in dPa s (or Poise, in line with conventional industrial usage) and T in $^\circ\text{C}$, whereas in the Fluegel fits, η is measured in Pa s and T in $^\circ\text{C}$.

While other equations for viscosity-temperature relationships have been developed (see, for example, Mauro *et al.*, 2009) in practice the VFT equation provides a good fit in the range of viscosities of interest to a commercial SLS glass producer.

Commercial forming of SLS glasses is a highly automated process. In the case of bottle production, after melting, refining and conditioning, sausage shaped “gobs” of glass produced from the feeder are formed using an IS (independent section) machine which typically consists of a set of 6–20 sections, each of which is capable of dealing with 1–4 gobs of glass. The glass gob is introduced into a blank mold where the neck and the finish as well as a hollow shape are produced by pressing (wide neck

Table 3 Parameters used to calculate A , B and T_0 in Eq. (1); where $A = \sum_{i=0}^n x_i a_i$, $B = \sum_{i=0}^n x_i b_i$ and $T_0 = \sum_{i=0}^n x_i t_i$ and x_i = weight fraction of oxide/weight fraction of silica

containers) or blowing (narrow neck containers). The resultant blank, also known as a parison, is then transferred to a second mold where the final shape is produced by blowing. The molds are made of cast iron and graphite based agents are used to ensure that the glass does not stick to the mold. After forming it is necessary to cool the glass in a controlled fashion through the glass transition region. This minimizes any residual stresses that would otherwise be frozen into the glass, and which could lead to early fracture. Commercially this process involves passing the glass through an annealing furnace, also known as an annealing lehr, in which the glass is reheated to $\sim 550^\circ\text{C}$ (the annealing point) and then is slowly cooled to the strain point (see Fig. 5). Once the glass has cooled to below the strain point it is no longer necessary to slow cool the glass. To aid performance hot and cold end coatings are applied to container glasses prior to entering and after exiting the annealing lehr respectively. The hot end coatings tend to be tin oxide or titania based and enable the lubricious cold end coatings to stick to the glass.

Most modern flat glass is produced by the float process wherein the glass melt is floated out over the surface of a bath of tin kept under a reducing H₂/N₂ atmosphere. The glass does not react with the tin although a small amount does diffuse into the glass surface that is in contact with the tin bath. The thickness of the glass is then determined by the rate at which the glass moves along the tin bath. Once the glass has cooled sufficiently to prevent deformation under its own weight it is lifted from the tin bath and then passes through the annealing lehr. Only after the glass ribbon exits the lehr is it cut into smaller sections. The float process enables the production of large sheets of flat glass with a high quality surface finish and has become the dominant process for flat glass production. Prior to the development of the float process a variety of drawing and polishing processes were utilized (Cable, 1999).

The equilibrium thickness of float glass, t_{gr} is given by considering a surface energy balance

$$\frac{\rho_g g t_g^2}{2} \left(1 - \frac{\rho_g}{\rho_t} \right) = \gamma_{ga} + \gamma_{gt} - \gamma_{ta} \quad (2)$$

where ρ_g and ρ_t are the glass and tin densities (2.5 Mg m^{-3} and 6.5 Mg m^{-3} respectively), γ_{ta} and γ_{gt} are the tin-air and glass-tin surface energies (both $\sim 0.5 \text{ J m}^{-2}$) and γ_{ga} is the glass-air surface energy ($\sim 0.35 \text{ J m}^{-2}$). Substituting these values into Eq. (2) gives an equilibrium thickness of 6.8 mm. Top rolls can be used to produce glass to control the ribbon speed and thus produce glass that is either thinner or thicker than the equilibrium thickness.

The modern ability to produce large volumes of flat glass via the float process has resulted in people forgetting that historically window glass was not very flat due to the limitations of historical “flat” glass production technologies, such as crown glass production. This has resulted in a common myth concerning the flow of old windows, such as those in European cathedrals, over time which simply does not reflect reality. Gulbitten *et al.* (2018) have calculated for a medieval glass composition from Westminster Abbey a maximum flow of $\sim 1 \text{ nm}$ over 10^9 years. The reason that old windows tend to be thicker at the bottom is simply that the glass panes were not uniformly thick in the first place and, when glazing a window, installing the thicker (and thus heavier) section at the bottom is intrinsically more stable.

Optical Properties of SLS Glasses

While SLS glasses are not primarily thought of as optical glasses their optical homogeneity and color are nevertheless important in a number of applications. For example, it is essential that windows, especially in vehicles, exhibit minimal optical distortion. To prevent optical distortion it is necessary that there is a high degree of chemically homogenization and also that there are minimal residual stresses in the glass, as both compositional variation and residual stresses affect the refractive index, which typically is ~ 1.5 for SLS compositions (see, for example, Shahid and Glasser, 1972). Chemical homogenization requires that the different fluids produced when the batch first melts are thoroughly mixed to enable diffusion as, under commercial SLS glass melting conditions, the

Table 4 Colors produced by some transition metal and rare earth ions in SLS glasses

<i>Species</i>	<i>Color</i>
$\text{Cr}^{3+}/\text{Cr}^{6+}$	Green/Yellow
$\text{Mn}^{2+}/\text{Mn}^{3+}$	Colorless/Purple
$\text{Fe}^{2+}/\text{Fe}^{3+}$	Blue green/Yellow
Co^{2+}	Blue
Ni^{2+}	Brown
$\text{Cu}^{+}/\text{Cu}^{2+}$	Colorless/Blue
$\text{Ce}^{3+}/\text{Ce}^{4+}$	Yellow/Colorless
Nd^{3+}	Purple

diffusion distances are only of the order of 0.1 mm. In commercial melting, mixing is achieved primarily through convection arising from temperature gradients along the length of the furnace; the use of electric boost and bubblers can also aid mixing.

Color in SLS Glasses

Color can be produced in SLS glasses by three major mechanisms: solution colors due to the presence of transition metals or rare earth elements, with transition metals giving stronger colors (see [Table 4](#)); absorbing particles that are typically, but not necessarily metallic; and phase separation to produce white or opal glasses.

For solution colors redox control during SLS glass manufacture is critical for achieving both the desired color and good quality glass. Iron is particularly important in the coloring of SLS glasses as it is a common contaminant in the raw materials, as well as small amounts being added as a dopant to produce specific colored and filter glasses. Iron is present in SLS glasses as both Fe^{2+} and Fe^{3+} ions and both ions can occupy tetrahedral and octahedral sites and fully modeling the color produced has to take into account both the redox chemistry and the site occupation ([Volotinen et al., 2008](#)). Fe^{3+} absorbs in the ultraviolet (UV) portion of the spectrum with the absorption band extending into the visible absorbing blue light and thus Fe^{3+} results in the glass having a yellow color. Meanwhile Fe^{2+} absorbs in the infrared (IR) with the absorption band again extending into the visible this time absorbing red light meaning that Fe^{2+} results in the glass appearing blue-green. As Fe^{2+} and Fe^{3+} produce complementary colors, with Fe^{2+} producing the stronger color, decolourisation can be achieved by adjusting the $\text{Fe}^{2+}:\text{Fe}^{3+}$ ratio through the addition of other redox species ([Parker, 2018](#)). Historically this was achieved by additions of As, which was actually added for refining purposes, with Ce being used more recently. An alternative approach, rather than making the melt more oxidizing, is to add Se to provide the complementary color to Fe^{2+} . Depending on the levels of iron present decolourisation may actually produce a glass which although apparently clear is in fact gray when compared visually with a glass that has a lower iron content.

For windows some degree of solar control can be achieved through the presence of iron in the glass, although the use of coatings is an industrially more flexible approach to this. For solar cell applications where very low losses due to absorption are required, the iron levels are reduced to ~ 100 ppm compared to ~ 1000 ppm in conventional float glass.

Amber glasses (see [Fig. 6](#)) involve the $\text{Fe}^{3+}\text{-S}^{2-}$ amber chromophore, which forms during cooling in reduced melts ([Beerken, 2005](#)), and which gives rise to strong absorptions at 295 nm and 425 nm (see [Fig. 6\(a\)](#)). Meanwhile green container glasses are usually colored by chromium (as Cr^{3+}) and iron with melting being carried out under oxidizing conditions – a range of greens can be produced from an emerald green through to an olive green. Lighter greens tend to be produced just using iron. As there is a correlation between the batch redox and the glass color, the batch redox number introduced by [Simpson and Myers \(1978\)](#) can be helpful. If glass melts are strongly colored then this reduces the radiation conductivity through the melt, and as a consequence electric boost may be required in the melting tank.

Absorbing particles are normally nanometric in size i.e., much smaller than the wavelength of light. As a result there is little light scattering but there is strong absorption even at concentrations of < 1000 parts per million (ppm). Examples include Ag which gives a yellow/orange color and Cu which gives a deep red. If the particles approach the wavelength of light in size then light scattering also occurs and this results in different colors in transmission and reflection, with scattering dominating in the latter case; the 4th century CE Roman Lycurgus cup is one of the most famous examples of this type of effect (see, for example, [Barber and Freestone, 1990](#)).

Unlike the other colored glasses mentioned above, white or opal glasses are designed to be opaque. They typically contain 1–5 wt% of precipitated particles that scatter the incident light, with the optimum particle size being about the wavelength of light. In fluoride opals these could be calcium, barium or sodium fluoride.

Photoelasticity and Stress Birefringence

Even though good quality annealed SLS glasses are optically isotropic, in the presence of stress SLS glasses become optically anisotropic and this leads to the production of colored fringes when the glass is observed between crossed polars in a polariscope or a strain viewer. The fringes are related to the principal stresses and two types of fringes can be formed; black isoclinics which give

Fig. 6 (a) Absorption spectra for colorless, dark olive and dark amber SLS glasses, based on data in Bingham, P.A., Connelly, A.J., Hand, R.J., *et al.*, 2010. A multi-spectroscopic investigation of sulphur speciation in silicate glasses and slags. *Glass Technology: European Journal of Glass Science and Technology A* 51, 63–80; (b) examples of colorless, amber and olive green container glasses.

information about the orientation of the principal stresses and colored isochromatics that are directly proportional to the difference in principal stresses. Analysis is most straightforward for plane stress situations when it can be shown that:

$$n\lambda = Ct(\sigma_1 - \sigma_2) \quad (3)$$

where n is the fringe order, λ is the wavelength, C is the stress optic coefficient which for SLS glasses is typically ~ 2.6 Brewsters ($1 \text{ Brewster} = 10^{-12} \text{ Pa}^{-1}$) although this does vary with composition (Hemsley, 2015), t is the glass thickness and σ_1 and σ_2 are the principal in-plane stresses. The analysis becomes more complicated for 3-dimensional objects as containers and integrated photoelastic techniques are required (Aben *et al.*, 2014).

Stress birefringence is used in the production environment to determine whether the levels of residual stress in the glass are acceptable and a range of automatic stress meters are available, as well as computer based integrated photoelastic systems. In the case of flat glass production inline photoelastic measurements can be used for ribbon control.

Chemical Durability

Both container and flat glass are required to have sufficient chemical durability to avoid obvious degradation in properties during use, where usage times can be decades or longer. For higher specification applications such as pharmaceutical containers this is measured in standards such as ISO 4802-1:2016 and in fact borosilicate glasses are usually preferred in such applications over SLS glasses due to their higher chemical durability.

The first stage of chemical attack by water involves ion exchange wherein hydronium (H_3O^+) ions exchange with the relatively mobile sodium (Na^+) ions in the glass network. As noted above calcium ions occupy the same type of sites within the glass network as sodium ions, but being doubly charged are less mobile and thus the replacement of soda by lime increases the chemical durability. The fact that in SLS glasses alumina is incorporated into the glass network as AlO_4^- tetrahedra, charge balanced by sodium ions, means that the presence of alumina reduces the mobility of sodium ions enhancing the chemical durability.

If there is limited water on the glass surface then the sodium ions will lead to an increase in the solution pH and eventually this can become sufficiently high that the Si–O–Si bond is subject to attack and congruent dissolution of the glass occurs. If this occurs on the interior surfaces of glass panes in a double glazing unit it can eventually lead to a clouding of the glass surface. Alternatively if the glass is exposed to an exterior environment then the sodium and calcium ions may react with atmospheric components to produce sulfates, carbonates or nitrates on the glass surface. Surface deposits can lead to localized attack and Bange *et al.* (2002) have reported notably different corrosion rates on SLS glass depending on whether the surfaces have been cleaned or not.

For window applications so called “self-cleaning” SLS glass products are available. These glasses have photocatalytic TiO_2 coatings which enable degradation of organic compounds that would otherwise be adsorbed onto the glass surface over time. Such compounds reduce the hydrophilicity of the glass surface and can act as a glue hindering the removal of surface contamination by rain. As a result such “self-cleaning” glasses exhibit a lower degree of surface contamination (soiling) over time (Verità *et al.*, 2007).

Chemical durability of glasses is a complex phenomenon and small compositional changes can have significant effects. For example, the presence of small amounts of tin on the side of float glass that was in contact with the float bath (the tin side) means that the durability of this side is notably better than the “air side” of the same glass as shown by a lower rate change of

Fig. 7 Nanohardness as function of depth and time of exposure to 95% relative humidity at 40°C of SLS float glass (a) tin side and (b) air side (selected data from Gonzalez Rodriguez, J.A., Hand, R.J., 2013. Evolution of the modulus and hardness of the tin and air sides of float glass as a function of hydration time. *Glass Technology: European Journal of Glass Science and Technology A* 54, 36–41).

Table 5 Typical mechanical properties of soda-lime-silica glasses

Mechanical property	Value
Young's modulus	70–75 GPa
Poisson's ratio	0.22–0.25
Fracture toughness	0.72–0.82 MPa m ^{1/2}
Hardness (Vickers)	5.4–6.6 GPa
Brittleness	6.5–9.0 μm ^{-1/2}
Thermal expansion coefficient	9.0–10.0 × 10 ⁻⁶ K ⁻¹
Stress corrosion <i>n</i> (power law fit)	14–16

the nanohardness with time when exposed to high temperature and relative humidity (see [Fig. 7](#) and [Gonzalez Rodriguez and Hand, 2013](#)).

Mechanical Properties

SLS glasses are hard brittle materials with low values of fracture toughness (see [Table 5](#)) hence they are flaw sensitive. If sufficient load is applied to an SLS glass object to cause fracture, cracking will normally initiate from surface defects introduced via unavoidable mechanical contact during either production and/or use. As a result SLS glasses and glass products do not have a single well-defined fracture strength and the strength of any particular glass object is likely to change with time, with practical strengths typically varying from ~30 MPa to ~100 MPa depending on the age and history of the glass surface. Using:

$$K_{Ic} = C\sigma_f\sqrt{\pi a} \quad (4)$$

where K_{Ic} is fracture toughness, σ_f is failure strength, a is flaw size and C is a constant (~ 1 for simple flaw geometries) indicates that typical surface defects in glass products are of the order of a few 10 s of microns in depth. Statistical methods are commonly required for describing glass strength with the Weibull statistics approach being widely used (see, for example, [Hand and Sangleboeuf, 2018](#)), although it may be equally appropriate to use the normal or log-normal distributions to describe the actual strength data.

Some variation of the mechanical properties of SLS glasses with composition have been reported (see, for example, [Sehgal and Ito \(1999\)](#), [Deriano et al \(2004\)](#), [Kilinc and Hand \(2015\)](#)). Many of the reported variations involve changes in minor components as well as some of the major components with [Sehgal and Ito \(1999\)](#) producing a so-called “less brittle glass” by replacing some of the soda by potassia, some of the lime by magnesia and some of the silica by alumina. Recent work indicates that the less-brittle SLS glass is more correctly described as being crack-resistant as the actual fracture toughness is little changed from that of conventional SLS glasses ([To et al., 2020](#)).

SLS glasses are relatively prone to mechanical failure through thermal shock failure as they have high thermal expansion coefficients (see [Table 5](#)) coupled with low thermal conductivities. Thus although chemical laboratory ware can be made of SLS glass, the lower thermal expansion borosilicate glasses are preferred.

For applications requiring higher strengths SLS glasses may be strengthened by introducing residual surface compressive stresses via thermal or chemical tempering. With flat glass, lamination into a composite structure can also reduce the likelihood of complete catastrophic failure and this approach is widely used in car windscreens and, sometimes in combination with thermal tempering, in architectural applications.

Thermal Tempering

Thermal tempering, which involves rapid cooling from above the glass transition temperature, is most readily applied to simple geometries and thus is most widely used with flat glass although it is used on some glassware as well. For full thermal tempering the maximum surface compressive stress (σ_c) in SLS glasses should exceed 69 MPa and can be up to ~ 100 MPa; the strength of glass components is increased by approximately the value of σ_c (Hand and Sangleboeuf, 2018). If the surface compressive stresses are lower ($24 < \sigma_c < 69$ MPa) then the product may be referred to as heat strengthened. Thin glass (< 3 mm thick) or more complex shapes are more likely to be heat strengthened than fully tempered.

The thermal tempering stress distribution is ideally parabolic and can be modeled by:

$$\sigma = \frac{\sigma_c}{2} \left(1 - \frac{12x^2}{d^2} \right) \quad (5)$$

where d is the thickness of the glass and x is the distance from the centreline. The residual surface compressive stresses decrease with depth and at $x \approx 0.21d$ the residual stresses become tensile and rise to 50% of the maximum surface compressive stress on the centerline. These high interior tensile stresses can cause failure from a defect known as nickel sulfide. In commercial glass production if there is a source of nickel present (sulfur will typically be present from either batch materials or the fuel) small droplets of nickel sulfide can be formed in the melt. These droplets are immiscible with the melt and are difficult to spot. While they do not cause a particular problem in annealed glass, the heat treatment and quenching process used to produce thermally tempered glass can result in them being retained as the metastable high temperature form, α -NiS. Subsequent heating through e.g., solar irradiation can then result in an expansive conversion to the low temperature β -NiS form. If this occurs in a region with high tensile residual stresses, interior microcracking and subsequent spontaneous failure can occur. This problem has arisen in a number of high profile buildings globally. It can be shown that there is a critical NiS inclusion size for this to occur, with larger inclusions being tolerated further from the centreline (Swain, 1981). To avoid this problem manufacturers try to prevent NiS formation in the first place and heat-soak tests are required to identify the problem before the glass is installed.

Chemical Tempering

Chemical tempering involves the replacement of alkali ions in the glass (Na^+ ions in SLS glasses) by larger alkali ions (K^+) through diffusional ion exchange. As chemical tempering is a diffusion based process it is slow and therefore expensive. Hence it is only commercially viable for high end products despite the fact that it can result in a much greater degree of strengthening than is possible with thermal tempering. For SLS glasses a potassium containing salt bath (typically potassium nitrate based) would be used to replace sodium ions by larger potassium ions at a temperature below the glass transition temperature. Much higher surface compressive stresses can be achieved with this technique than is possible with thermal tempering but they are limited to a thin surface layer (the case depth) due to the diffusional nature of the production process. As a result the compensating interior tensile stresses are much lower than is the case with thermally tempered glass. The high surface compressive stresses mean that practical glass strengths can be increased to several hundred MPa for SLS glasses.

Sub-Critical Crack Growth

SLS glasses are susceptible to slow crack growth due to stress corrosion under applied load in the presence of atmospheric water. As shown in Fig. 8(a) the crack velocity, v , is a strong function of the applied stress intensity factor, K_I , given by:

$$K_I = C\sigma\sqrt{\pi a} \quad (6)$$

where σ is the applied stress with the other terms as defined previously (see Eq. (4)). Fig. 8(a) shows that there are 4 distinct regions; namely a threshold ($K_{I_{th}}$) below which stress corrosion does not occur; then a region labeled I during which crack growth is controlled by the reaction between water and the strained Si–O–Si bonds at the crack tip; a plateau region labeled II in which the rate at which water can diffuse to the crack tip becomes important and region III where the transition to fast fracture takes place and the applied stress intensity factor becomes equal to the fracture toughness K_{Ic} . Region I may be fitted using an exponential:

$$v = \frac{da}{dt} = \alpha \exp(K_I), \quad (7)$$

where α is a constant, or a power law function:

$$v = \frac{da}{dt} = AK_I^n, \quad (8)$$

where A and n are both constants. Although the power law description is a purely empirical description it is easier to use when

making lifetime predictions. There is disagreement in the literature as to whether there is a clear threshold below which stress corrosion does not occur in SLS glasses with available data indicating a dependence on both relative humidity and test technique (see Fig. 8(b)).

Such sub-critical growth is responsible for the gradual extension of cracks from e.g., impact chips on car windscreens or from edge defects in windows in a frame. In the former case, coatings to repair such damage and prevent sub-critical crack growth are available in the market.

Summary

Soda-lime-silica glasses have been very widely used since ancient times to produce containers, windows and glassware as the raw materials required to produce them are readily available and relatively cheap. By controlling temperature and hence viscosity SLS glasses can be readily formed using highly automated production techniques. Although a wide range of SLS glass compositions can be produced, the relatively narrow range of compositions used commercially represents a good balance between processability and final properties including chemical durability. With suitably pure raw materials very clear glass can be produced, particularly if the iron content can be minimized. Iron plays an important role in the color of container glasses. Color can also be produced through the addition of other dopants, usually in relatively small quantities. As soda-lime-silica glasses have low fracture toughness values the mechanical strength of SLS products is usually controlled by the presence of small surface flaws. In the presence of water such flaws can grow sub-critically due to stress corrosion. The mechanical strength may be improved through the use of residual stresses, introduced via thermal or chemical tempering. Lamination may also be used to provide an additional level of safety if one layer fails.

Glasses: Aluminosilicates

Laurent Cormier, Sorbonne University, Paris, France

© 2021 Elsevier Inc. All rights reserved.

Aluminosilicate glasses are widely used and investigated materials with current and promising technological applications such as high-power laser gain media, flat-panel displays, solid oxide fuel cells, sealing materials, glass-fiber composites and long-term immobilization of wastes, to name a few. They are also abundant in nature and relevant for geological processes as they are chemically close to the natural magmatic compositions of the Earth mantle. Finally at low SiO_2 content, quenched metallurgical slags are mainly composed of aluminosilicate glasses. Introducing Al_2O_3 strongly affects many physico-chemical properties. For instance, it improves fracture strength, increases elastic modulus and chemical resistance or hinders the trend to phase separation. Many properties correlate with the nature of non-framework cations present in the glass and to the flexibility for Al to adopt multiple coordination states. Different aspects of the disorder (network connectivity, Si/Al disorder, short range environment) affect the topological and configurational entropies. Here we address the specificities of the atomic-scale structure in diverse glass models containing alumina with important implications for interpreting and controlling the physico-chemical properties.

Commercial Glasses

Aluminosilicate (AS) glasses, notably at low-alkali content, have high values of tensile strength, resistance to high temperature and excellence resistance to chemical corrosion (Varshneya and Mauro, 2019). They have found widespread commercial application as fibers to reinforce plastics or concrete. E-glass (a low-alkali Ca-Mg aluminoborosilicate glass with 10–15 mol% Al_2O_3) is the most common glass fibers. Nowadays, a major application concerns alkali-free aluminosilicates used as thin glass sheets for liquid crystal flat displays.

With higher amounts of alkalis, aluminosilicate glasses can be used to obtain high surface strength via an ion exchange process. The chemical exchange (typically Na replaced by K) produces a permanent compressive stress in the glass surface that improves resistance to cracks and scratches. This type of glass is exploited in smartphone screens or aircraft windshields and further applications (for instance in automotive) are foreseen. Alkali or alkaline-earth aluminosilicate systems are also the precursor glasses for most glass-ceramics successfully designed for consumer applications.

Al_2O_3 , The Archetypical Intermediate Oxide

Al_2O_3 itself cannot form a glass as it does not satisfy the rules proposed by Zachariasen (1932) for a network former. However, a specificity of Al_2O_3 is to be able to form a glass when it is mixed with some modifying cations (typically alkaline earths or rare-earths). Sun (1947) has classified Al_2O_3 as an intermediate oxide acting as network former or modifier according to the composition. Indeed, Al_2O_3 can be added into the vitreous silicate network by replacing Si^{4+} cations in a tetrahedral environment. In that case, it plays the role of a network former and even small amounts of Al_2O_3 considerably modify the glass properties. Alternatively, Al can enter into high coordinated sites, playing the role of a modifier.

Basic Structural Features

Al in Substitution for Si

Si is a network former occurring as SiO_4 tetrahedra in oxide glasses. In aluminosilicate glasses, Al has a strong preference for tetrahedral coordination and usually substitutes for Si in tetrahedral positions, behaving similarly to a network former. An Al^{3+}O_4 tetrahedron has a charge deficit compared to a Si^{4+}O_4 unit because only three positive charges are brought by Al^{3+} cations. The electrical balance and the stabilization of $(\text{AlO}_4)^-$ tetrahedra are ensured by introducing positive charges brought by alkali (M^+), alkaline earth (M^{2+}) or rare-earth (RE^{3+}) cations. The cations compensating the net negative charge on $(\text{AlO}_4)^-$ units are called charge compensators (or charge-balancing cations), as opposed to a network modifying role when they are associated with non-bridging oxygen atoms (NBOs), participating in this latter case to the loss of network connectivity (depolymerization). A schematic representation of the addition of Al_2O_3 in a silicate glass network is shown in Fig. 1. The introduction of Al_2O_3 results in less NBOs (and thus more bridging oxygen atoms, BOs) and increases network connectivity. As a consequence the network becomes more stiff, the viscosity and the glass transition temperature (T_g) increase.

Since the Al-O bond length (1.76 Å) is longer than for Si-O (1.62 Å) (Cormier et al., 2000b), the AlO_4 tetrahedron is bigger than SiO_4 . The replacement of Si by Al then modifies the network organization and changes the glass physico-chemical properties. Raman spectroscopic investigations of aluminosilicate glasses (Mysen, 1990) revealed that increasing the Al/Si ratio implies a decrease in the force constant due to the weakening of the T-O bonds ($T = \text{Si}$ or Al) when Al substitutes for Si. The structure of aluminosilicate glasses largely depends on the arrangement of SiO_4 and AlO_4 tetrahedra that are forming a skeletal network by corner-sharing through bridging oxygen (BO) atoms.

Fig. 1 Schematic representation of replacement of $\frac{1}{2}\text{Na}_2\text{O}$ by $\frac{1}{2}\text{Al}_2\text{O}_3$, resulting in a pair of non-bridging oxygens replaced by one bridging oxygen.

Fig. 2 Changes of the ^{29}Si chemical shifts for the various $Q^n_{\text{Si}}(m\text{Al})$ units in aluminosilicate glasses, as proposed by Engelhardt, G., 1989. Multinuclear solid-state NMR in silicate and zeolite chemistry. Trends in Analytical Chemistry 8, 343–347. doi:10.1016/0165-9936(89)87043-8.

The network connectivity is efficiently probed by Magic-angle spinning (MAS) nuclear magnetic resonance (NMR) spectroscopy. The NMR chemical shift of ^{29}Si is sensitive to the degree of connectivity of the SiO_4 tetrahedra represented by the Q^n notation with n the number of BO on a tetrahedron. The decreasing number of BO displaces the chemical shift to higher values. The Si/Al substitution causes an additional modification of the chemical shift depending on the number m of Al atoms as second neighbors (**Fig. 2**). The moieties for Si and Al are denoted $Q^n_{\text{Si}}(m\text{Al})$ and $Q^n_{\text{Al}}(m\text{Si})$, respectively, indicating m Si–O–Al or Al–O–Si bonds (Edén, 2015). A Q^3_{Si} unit with a negative charge (-2) and one NBO requires a greater number of charge balancing cations in its neighborhood compared to a Q^3_{Si} with a charge (-1). The fully connected Q^4_{Al} species (charge -1) are then favored. Though the different $Q^n_{\text{Si}}(m\text{Al})$ moieties strongly overlap in the ^{29}Si NMR signal, advanced NMR techniques allow the relative amounts of these species to be fully quantified (Hiet *et al.*, 2009).

Another important structural feature is to determine the extent of Si/Al ordering that can be revealed by ^{17}O NMR. This spectroscopy gives access to the various linkages between BO atoms and framework cations, i.e., $^{14}\text{Si-O-}^{14}\text{Si}$, $^{14}\text{Si-O-}^{14,5}\text{Al}$, and $^{14}\text{Al-O-}^{14,5}\text{Al}$. Extensive Si/Al mixing, reflecting chemical order, results in a high fraction of $^{14}\text{Si-O-}^{14}\text{Al}$, whereas a tendency toward disorder leads to high fractions of $^{14}\text{Al-O-}^{14}\text{Al}$ and $^{14}\text{Si-O-}^{14}\text{Si}$ (Lee and Stebbins, 2002).

Al Avoidance Principle

According to the Loewenstein's rule (Loewenstein, 1954), also known as the Al-avoidance principle, there is a strong preference for $^{14}\text{Si-O-}^{14}\text{Al}$ linkages, whereas those of $^{14}\text{Al-O-}^{14}\text{Al}$ are energetically less favorable and avoided due to the local negative charge-accumulation. This rule governs the distribution of framework cations within the network but it seems to suffer many exceptions in alkali/alkaline-earth/rare-earth aluminosilicate glasses (Lee and Stebbins, 1999, 2000a; Lee *et al.*, 2005; Moesgaard *et al.*, 2010; Jaworski *et al.*, 2015). The framework disorder is quantified by the $Q^n_{\text{Si}}(m\text{Al})$ moieties or the oxygen cluster population, T-O-T, that both can be ascertained experimentally using MAS NMR spectroscopy of ^{29}Si and ^{17}O nuclei and confirmed with many molecular dynamics (MD) simulations (Lee and Stebbins, 1999, 2000a, 2002; Lee *et al.*, 2005; Lee and Stebbins, 2006; Moesgaard *et al.*, 2010; Park and Lee, 2012; Jaworski *et al.*, 2015).

To quantify the abundance of Si/Al intermixing, the degree of Al avoidance (Q) was proposed, spanning from complete chemical order ($Q = 1$, complete Al avoidance) to a random distribution of Si and Al ($Q = 0$) (Lee and Stebbins, 1999, 2002). At low Al_2O_3 content, obedience to the Loewenstein's rule is generally valid and implies a non-random mixing of network forming cations (Ando *et al.*, 2018; Ganisetti *et al.*, 2019). However, the proportion of Al–O–Al and Si–O–Al linkages increases with increasing connectivity as more Al_2O_3 is introduced at constant silica content (Lee and Stebbins, 2006, 2009). For instance, chemical ordering ($Q = 0$) is prevalent in Na aluminosilicate compositions except for compositions with $\text{Na}_2\text{O}/\text{Al}_2\text{O}_3 = 1$, emphasizing that the Si/Al ordering behavior depends on composition (Na/Si or Si/Al ratios) (Lee and Stebbins, 2000b; Lee *et al.*, 2005; Iftekhar *et al.*, 2009; Lee and Stebbins, 2009; Park and Lee, 2014). Increasing fictive temperatures tend to increase Al–O–Al linkages (Dubinsky, 2006). The size and valence of non-framework cations have also a considerable influence and this effect can be rationalized using the cation field strength, CFS, defined as z/r^2 , with z the cation valence and r the ionic radius

Fig. 3 Effect of cation field strength, CFS, on the degree of Al avoidance, Q . Data from Lee, S.K., Kim, H.-I., Kim, E.J., Mun, K.Y., Ryu, S., 2016. Extent of disorder in magnesium aluminosilicate glasses: Insights from ^{27}Al and ^{17}O NMR. *The Journal of Physical Chemistry C* 120, 737–749. doi:10.1021/acs.jpcc.5b10799.

(Shannon, 1976). Since high CFS favors negative charge concentration, Al atoms tend to be closer and the probability of finding Al-O-Al linkages increases with CFS: RE > Mg > Ca > (Ba, Li) > Na > (K, Rb, Cs) (RE = rare earth) (Stebbins *et al.*, 1999; Lee and Stebbins, 2000a,b; Kelsey *et al.*, 2008; Jaworski *et al.*, 2012; Okhotnikov *et al.*, 2013; Lee *et al.*, 2016). Therefore, RE-aluminosilicate glasses display the highest degree of randomness in their Si/Al distribution (Iftekhar *et al.*, 2009). Breakdown of the Al avoidance is confirmed by several MD simulations (Stein and Spera, 1995; Cormier *et al.*, 2003; Ando *et al.*, 2018; Ganiseti *et al.*, 2019). The effect of CFS on the degree of Al avoidance is shown in Fig. 3 for alkali/alkaline earth cations (Lee *et al.*, 2016). The extent of chemical ordering (Q) manifests a linear decrease with CFS ($Q \approx -0.1 \times \text{CFS} + 1$). It is expected that this simple relationship could not be valid for glasses with higher CFS and/or with RE, with a deviation from the linear trend (Lee *et al.*, 2016).

Aluminosilicate Glass Models

For tectosilicate compositions ($M^{n+}/n\text{Al} = 1$), the fully interconnected network is described by the “Compensated Continuous Random Network” (CCRN) model (Greaves and Ngai, 1995a). The modified random network (MRN) model is used to describe Al_2O_3 -free glasses and imply a micro-segregation of modifiers with the co-existence of two sub-networks: one rich in modifiers and NBOs and another one rich in network formers. For peralkaline(-earth) glasses ($M^{n+}/n\text{Al} > 1$), an intermediate structure between CCRN and MRN prevails. Si^{4+} and Al^{3+} cations are essentially organized in a corner-sharing tetrahedral network with NBOs mainly connected to Si atoms. The M^{n+} cations not used to neutralize the charge-imbalance from $(\text{AlO}_4)^-$ tetrahedra promote the formation of NBOs. Percolating channels similar to those existing in the MRN models have also been proposed in aluminosilicate glasses (Sukenaga *et al.*, 2017; Le Losq *et al.*, 2017). To further consider the distribution of framework units and the violation of the Loewenstein’s rule in aluminosilicate glasses, an extended modified random network (EMRN) model was proposed (Allu *et al.*, 2018; Ganiseti *et al.*, 2019). According to this model, three regions co-exist (Fig. 4): a depolymerized channel region (similar to MRN) and a $\text{SiO}_4/\text{AlO}_4$ network structure region that is separated in “heteronuclear” (mainly Si-O-Al and Al-O-Al) and “homonuclear” (mainly Si-O-Si) regions. M^{n+} cations acting as charge compensator favor the formation of Si-O-Al heteronuclear regions, whereas M^{n+} cations acting as modifiers are associated with several Si-NBO forming depolymerized regions. The Si atoms in excess of Si-O-Al and Si-NBO bonds form SiO_4 -rich “homopolar” regions.

Local environment around Al – Over coordinated Al

Al in tetrahedral coordination is predominantly present in aluminosilicate glasses as in most minerals, zeolites and ceramics. The aluminum environment has been investigated using many experimental techniques: Raman spectroscopy (Brawer and White, 1977; McKeown *et al.*, 1984), X-ray absorption spectroscopy (McKeown *et al.*, 1985; Landron *et al.*, 1992; Wu *et al.*, 1999; Sen, 2000; Neuville *et al.*, 2004b; Moulton *et al.*, 2016) and NMR (McMillan and Kirkpatrick, 1992; Stebbins *et al.*, 2000; Toplis *et al.*, 2000; Neuville *et al.*, 2006).

The phase diagram of a $\text{M}_{2/n}\text{O}-\text{Al}_2\text{O}_3-\text{SiO}_2$ system ($n = 1, 2$) can be divided in two domains called peralkaline(-earth) for a ratio $R = M^{n+}/n\text{Al} > 1$ and peraluminous for a ratio $R = M^{n+}/n\text{Al} < 1$. The line $R = 1$ separating these two domains is called the “charge compensation” or “charge balanced” join corresponding to tectosilicate compositions. In the peralkaline(-earth) field ($R > 1$), the concentration of M^{n+} cations allows the full compensation of the charge deficit of each $(\text{AlO}_4)^-$ tetrahedron and Al^{3+} , stabilized in tetrahedral position, behaves as a network former similar to Si^{4+} . M^{n+} cations in excess relative to Al^{3+} play a network modifying role and introduce NBOs into the structure. When R decreases, the number of NBOs decreases and the glass network connectivity increases. In principle, when $R = 1$, no more NBOs should remain in the glass network, all Al^{3+} atoms are

tetrahedrally coordinated and the network is fully connected. In the peraluminous domain ($R < 1$), a deficit in the number of charge compensators does not allow the stabilization of all AlO_4 tetrahedra. Consequently, higher coordinated species (five-fold coordination $[^5]Al$ or six-fold coordination $[^6]Al$) or O triclusters can be present.

However, the emergence of high field NMR in the beginning of 2000s led to a reconsideration of this simple structural picture. The presence of NBOs for glasses along the charge compensation join has been detected by ^{17}O NMR (Stebbins and Xu, 1997). Furthermore, numerous high-resolution solid-state ^{27}Al NMR studies (Toplis *et al.*, 2000; Neuville *et al.*, 2004b; Lee *et al.*, 2004; Neuville *et al.*, 2006, 2007; Allwardt *et al.*, 2007; Neuville *et al.*, 2008; Kelsey *et al.*, 2008; Xue and Kanzaki, 2008; Iftekhar *et al.*, 2012; Jaworski *et al.*, 2012; Park and Lee, 2012, 2014; Le Losq *et al.*, 2014; Novikov *et al.*, 2017) have inarguably revealed that aluminum is present in highly coordinated sites (i.e., five and six-fold coordination, $[^5]Al$ and $[^6]Al$) even in the peralkaline(-earth) domain or along the charge compensation join (Fig. 5). The formation of $[^5]Al$ is clearly favored over that of $[^6]Al$ and both populations of $[^5]Al$ and $[^6]Al$ change with pressure, temperature, composition (Si/Al or M/Al ratios) or with the nature of M^{n+} cations. Aluminum coordination increases under static or dynamic compression, particularly in depolymerized glasses (Sato *et al.*, 1991; Yarger *et al.*, 1995; Lee, 2004; Lee *et al.*, 2004; Allwardt *et al.*, 2005a,b; Kelsey *et al.*, 2009; Lee, 2010; Bista *et al.*, 2015). The effect of temperature has been studied in situ or by varying the quenching rate (Sato *et al.*, 1991; Kanehashi and Stebbins, 2007; Florian *et al.*, 2007; Stebbins *et al.*, 2008; Thompson and Stebbins, 2013; Le Losq *et al.*, 2014). The proportion of $[^5]Al$ tend to increase with increasing temperature (in situ measurement) or fictive temperature (obtained when varying the quenching rate) but the variations are small compared to the effect of pressure. The fraction of $[^5,6]Al$ sites strongly depends on the CFS of non-framework cations with high CFS favoring large population of $[^5,6]Al$ (Fig. 6) (Neuville *et al.*, 2008; Kelsey *et al.*, 2008; Iftekhar *et al.*, 2012; Jaworski *et al.*, 2012). The higher content of $[^5,6]Al$ is also observed for RE-aluminosilicate and Zn-aluminosilicate glasses but these cations seems to follow a different trend (Schaller and Stebbins, 1998; Florian *et al.*, 2007; Iftekhar *et al.*, 2012; Jaworski *et al.*, 2012, 2015; Cormier *et al.*, 2021).

The average cationic potential has been proposed to account for changes in $[^5,6]Al$ fractions with composition (Park and Lee, 2014). The average cationic potential is the ratio of charge (c) to ionic radius (r) normalized by the mole fraction of each non-network cation:

$$\langle c/r \rangle_{ave} = \sum_i x_i \frac{c_i}{r_i}$$

where x_i , c_i and r_i are the mole fraction, the charge and the ionic radius of cation i , respectively. Park and Lee (2014) have summarized (Fig. 7) the population of $^{[5,6]}\text{Al}$ as a function of $\langle c/r \rangle_{\text{ave}}$ in all the ternary or multi-component aluminosilicate glasses studied so far. The population of $^{[5,6]}\text{Al}$ shows an increasing trend when $\langle c/r \rangle_{\text{ave}}$ increases. A threshold is observed at $\langle c/r \rangle_{\text{ave}} = 2$ with a significant increase of the fraction of $^{[5,6]}\text{Al}$ above this value but with considerable dispersion. This is explained because, at a constant $\langle c/r \rangle_{\text{ave}}$, the population of $^{[5,6]}\text{Al}$ strongly depends on both $\text{M}^{n+}\text{O}_{n/2}/\text{Al}_2\text{O}_3$ and Si/Al ratios (Neuville *et al.*, 2006, 2008; Kelsey *et al.*, 2008; Thompson and Stebbins, 2012).

Each $(\text{AlO}_6)^{3-}$ octahedron is commonly considered as composed of three BOs and three NBOs (Day and Rindone, 1962) and has a network modifying character. Its content is always small compared to $^{[5]}\text{Al}$ because packing requirements for octahedral Al are unfavorable (Lacy, 1963). Conversely, the structural role of $^{[5]}\text{Al}$ as either a network former or a network modifier remains a fundamental debated question (Takahashi *et al.*, 2015). Using MD simulations of Ca-AS glasses, the bond angle distributions of AlO_5 (and SiO_5) units have been analyzed (Wiles *et al.*, 2020), revealing that $^{[5]}\text{Al}$ and $^{[5]}\text{Si}$ environments are consistent with the range of configurations found in a Berry pseudorotation (motion between two trigonal bipyramidal configurations). As $^{[5]}\text{Al}$ sites adopt any environment between the two extreme geometries with a minimal energy cost, the presence of $^{[5]}\text{Al}$ can likely play a governing role in mechanisms of plastic deformation or viscous flow. Similar to $^{[5]}\text{Si}$, $^{[5]}\text{Al}$ could be a transient species, thermally activated, that facilitates the diffusion of NBOs and the exchange of T–O bonds (Stebbins and Farnan, 1992; Farnan and Stebbins, 1994; Neuville *et al.*, 2007). Increasing the fraction of higher coordinated species can help to explain low viscosity at high pressure and reduced viscosities at high temperature (Lee *et al.*, 2004; Allwardt *et al.*, 2007; Wiles *et al.*, 2020). Furthermore, glasses with low hardness tend to have high $^{[5]}\text{Al}$ fractions (Iftikhar *et al.*, 2012; Svensson and Edén, 2013; Lamberson, 2016), suggesting that higher coordinated species could improve mechanical properties.

Oxygen Tricluster

As NBOs have been unexpectedly reported in compositions along the charge balancing joins (Stebbins and Xu, 1997), oxygen triclusters, O_{tri} , were proposed together with highly coordinated Al to maintain the network charge neutrality. By definition, O_{tri} is a special configuration of triply coordinated oxygen, $^{[3]}\text{O}$, only bonded to three tetrahedra (Fig. 8(a) and (b)): one AlO_4 and two SiO_4 or two AlO_4 and one SiO_4 (for this latter case a charge compensator is required in close proximity to maintain charge neutrality). Oxygen atoms coordinated to three, highly charged, tetrahedral cations are in strongly energetic configurations and violate Zachariasen's rules as O atoms are bonded to three network formers. A tricluster configuration can be regarded as an Al^{3+} ion acting as a modifier ion and bonded to NBOs (Fig. 8(c)).

The presence of triclusters results in a more compact packing and, thereby, higher densities are expected (Toplis *et al.*, 1997b). More importantly, triclusters can play a dominant role in transport properties, particularly for self-diffusion of oxygen in melts and viscous flow processes (Toplis *et al.*, 1997b). However, their presence is still debated and their influence on properties not ascertained (Tandia *et al.*, 2011). O_{tri} are mostly supported by MD simulations using classical (Cormier *et al.*, 2003; Barbieri *et al.*, 2004; Tandia *et al.*, 2011; Bouhadja *et al.*, 2014; Agnello *et al.*, 2019) or ab initio approaches (Benoit *et al.*, 2005). Experimentally, they have been detected only in a calcium aluminate glass using advanced NMR methods (Iuga *et al.*, 2005).

The Main Aluminosilicate Systems

Many different glasses can be obtained with aluminum and sometimes an extremely wide range of compositions can be achieved compared to the few crystalline compositions. Richet *et al.* (2006) have reviewed the glass forming regions in several important

Fig. 8 Common oxygen shared between three tetrahedra: (a) one SiO₄ and two AlO₄ or (b) two SiO₄ and one AlO₄. (c) Al³⁺ in tetrahedral environment, equivalent to (b), with one O tricluster (O_{tri}) and three NBOs in the first coordination shell.

alkali/alkaline earth systems, showing a close connection between glass forming ability (GFA) and viscosity, low liquidus temperature and low configuration heat capacity. The main important families of glasses containing Al₂O₃ are documented in this part, by outlining the current structural knowledge in relation to their important physico-chemical properties.

Aluminate Glasses

Binary aluminate glasses are remarkable materials as they are free of typical glass network forming oxides but contain a high proportion of alkaline-earth or RE oxides. They have excellent mechanical properties (Rosenflanz *et al.*, 2004; Johnson *et al.*, 2005; Rosales-Sosa *et al.*, 2015, 2018), high softening points (Johnson *et al.*, 2005) and some of the highest sound speeds of any glassy systems (Yeganeh-Haeri *et al.*, 1998). Vickers hardness ($H_v = 9.5$ GPa) and elastic modulus ($E = 158$ GPa), reported for a 46Ta₂O₃–54Al₂O₃ glass, are among the highest values among oxide glasses (Rosales-Sosa *et al.*, 2015). Molten aluminates have viscosities that do not follow an Arrhenius behavior and are thus classified as “fragile” (Wallenberger and Brown, 1994; Weber *et al.*, 1998). The fragility of these systems is related to a large configurational entropy as many structural states are available in liquids due to possible change in cationic environment.

Calcium aluminate (CA) glasses are attractive due to a promising infrared (IR) transparency up to $\lambda = 6$ μm (Hafner *et al.*, 1958; Higby *et al.*, 1990; Sung and Kwon, 1999), similar to sapphire. With small SiO₂ doping, they can have ultralow optical losses compared to pure SiO₂ (0.04 dB km^{−1} for a SiO₂-low CA glass compared to 0.16 dB km^{−1} for SiO₂ at 1.55 μm (Lines *et al.*, 1989)). A high elastic modulus of 125 GPa was reached for a ZnO-CA glass-fiber (Wallenberger and Brown, 1994), higher than that of a S-glass (87 GPa) that is the high-strength glass-fiber exploited for reinforcement composites. Such properties make CA glasses of considerable technological value for diverse applications (laser windows, IR domes or windows, IR fiber optics) (Wallenberger and Brown, 1994; Weber *et al.*, 1998; Hwa, 1998). CA glasses are also important as analog systems of metallurgical slags and hydraulic cements (Skibsted *et al.*, 1993; Poe *et al.*, 1994; Douy and Gervais, 2000).

CA glasses can be synthesized using a conventional furnace and quenching rate in a narrow range near the eutectic composition (64CaO–36Al₂O₃, CA36) (Sung and Kwon, 1999). A wider glass formation range (20–80 mol% CaO) can be accessed using containerless methods such as aerodynamic levitation coupled with laser heating (McMillan and Piriou, 1983; Weber *et al.*, 2002; Benmore *et al.*, 2003; Neuville *et al.*, 2010). A technique using solar furnace melting and splat quenching has allowed glasses with fast quenching rates of 10⁶–10⁷ K s^{−1} to be obtained (McMillan and Piriou, 1983; McMillan *et al.*, 1996). The GFA of CA can also be enhanced by addition of various oxides, improving the glass stability and reducing the presence of hydroxyl bonds (Onoda and Brown, 1970; Shelby *et al.*, 1989; Uhlmann *et al.*, 1993; Shelby and Wierzbicki, 1995).

From Al₂O₃-poor glasses to the tectosilicate composition (CaO > 50 mol%), tetrahedrally coordinated Al is the only species detected by high resolution ²⁷Al NMR and Raman spectroscopies, with no change whatever to the quenching rate (McMillan and Piriou, 1983; McMillan *et al.*, 1996; Neuville *et al.*, 2006, 2010). Addition of CaO progressively disrupts the fully-connected network of AlO₄ tetrahedra in CA50 glass (50CaO–50Al₂O₃) and reduces the O coordination (Akola *et al.*, 2013; Edén, 2015). The average oxygen coordination number (CN) around Ca is mainly determined by numerous X-ray and neutron diffraction studies and shows a rather wide range of values from 4 to 5.5 for similar CA compositions between CA30 and CA50 (Morikawa *et al.*, 1983; Hannon and Parker, 2000; Cormier *et al.*, 2000b; Mei *et al.*, 2008a,b; Drewitt *et al.*, 2011; Benmore *et al.*, 2003), probably due to an asymmetric distribution of O neighbors around Ca. MD simulations give a higher average CN of 6, with a wide range of distribution of Ca sites, for various CA glasses (from CA75 to CA25) (Kang *et al.*, 2006; Thomas *et al.*, 2006; Drewitt *et al.*, 2011) but the choice of potentials appears to have a major influence on the estimation of CN for Al and Ca. The role of Ca is not clear but it was proposed that this cation behaves as a network former together with Al (Benmore *et al.*, 2003). Recently, by using a combination of DFT and RMC simulations, the CA36 glass has been described as a topologically disordered cage network with a wide ring size distribution and many large-sized rings (Akola *et al.*, 2013). This structural organization differs from that of CA50

glass and could reflect the high GFA of glasses near the eutectic composition. When $\text{CaO} \leq 50$ mol%, high Al coordinated species $^{[5,6]}\text{Al}$ and O_{tri} begin to appear (McMillan *et al.*, 1996; Iuga *et al.*, 2005; Neuville *et al.*, 2006; Mei *et al.*, 2008a) and these species can also be observed in MD simulations (Drewitt *et al.*, 2011). Using $\{^{17}\text{O}\}\{^{27}\text{Al}\}$ HMQC (heteronuclear multiple quantum correlation) NMR experiments, the formation of $\sim 5\%$ O_{tri} has been evidenced in a CA50 glass (Iuga *et al.*, 2005). Edge or face-sharing AlO_4 units could also be present in Al_2O_3 -rich compositions based on specific Raman bands at $\sim 620\text{ cm}^{-1}$ and 430 cm^{-1} (McMillan and Piriou, 1983).

Structural defects (for instance superoxide O_2^- ion radical or peroxy -O-O- linkages; see Hosono and Abe, 1987) appear to be very specific to CA glasses close to the eutectic and they could explain high photosensitivity to ultraviolet rays (Hosono *et al.*, 1985). Quenching a CA37 melt in strongly reducing conditions has allowed the synthesis of an electride glass, C12A7: e^- (Kim *et al.*, 2011), that contains stabilized solvated electrons trapped in cages of the CA network, which could give a potential glassy electronic conductor. Based on DFT-RMC simulations of CA37 glass, the structural origin of these solvated electrons was proposed to be due to efficient elemental mixing resulting from similar atomic charges for Al and Ca and a network cage structure resulting from considerable fraction of large-sized rings that can host solvated electrons (Akola *et al.*, 2013). However, since the glass transition temperatures of C12A7: e^- glass ($T_g = 973\text{ K}$) radically differs from that of the oxidized glass ($T_g = 1133\text{ K}$) (Kim *et al.*, 2011), fundamentally different structures can be alternatively expected (Edwards, 2011).

Other alkaline-earth glasses obtained using containerless techniques have been investigated: Ba and Ba-Ti aluminates (Skinner *et al.*, 2006, 2012), Ba and Sr aluminates (Alahache, 2011; Licheron *et al.*, 2011), showing glass forming regions in various ranges for Ba (33–37 and 62–75 mol% BaO) and Sr (37–40 and 55–75 mol% SrO). Only glasses with excess of alkaline-earth oxides have been investigated revealing the expected network of corner-sharing AlO_4 tetrahedra.

Rare-earth (RE) aluminates are another class of glasses of high interest due to their luminescence properties, offering potential applications, particularly in the field of white light-emitting diodes. The GFA of these compounds is low and they are mainly prepared using contactless conditions (Weber *et al.*, 1998; Zhang and Navrotsky, 2004; Watanabe *et al.*, 2012). According to Watanabe *et al.* (2012), RE aluminate glasses can be obtained between $0.20 < \text{RE}_2\text{O}_3$ (mol%) < 0.5 and all systems form glasses for 30–32 mol% RE_2O_3 . The glass forming region increases with the RE^{3+} ionic radius and is the widest for the La_2O_3 - Al_2O_3 system (27–50 mol%).

Y_2O_3 - Al_2O_3 (YA) glasses have attracted special interest as a potential glassy laser host (similar to crystalline $\text{Y}_3\text{Al}_5\text{O}_{12}$ garnet, the so-called YAG) and as a system displaying a variety of non-equilibrium phenomena (McMillan *et al.*, 2003; McMillan and Wilding, 2008). Yttrium aluminate glasses were synthesized in the range of 0.2–0.4 mol% Y_2O_3 by aerodynamic levitation or in an iridium wire furnace (Tangeman *et al.*, 2004; Skinner *et al.*, 2008; Nasikas *et al.*, 2011). YA glasses and their melts have been the subject of numerous studies due to the possible existence of polyamorphism in this system (Wilding and McMillan, 2001; Wilding *et al.*, 2002a,b; Wilding and McMillan, 2002; McMillan *et al.*, 2003; Tangeman *et al.*, 2004; Weber *et al.*, 2004; McMillan and Wilding, 2008; Skinner *et al.*, 2008; Greaves *et al.*, 2008; Barnes *et al.*, 2009; Greaves *et al.*, 2009; Nasikas *et al.*, 2011). Aasland and McMillan (1994) have observed the coexistence of two glassy states of identical composition but different structures, densities and thermodynamic properties (Fig. 9). Using differential scanning calorimetry, two glass transition temperatures were determined at $\sim 1135\text{ K}$ and 1300 K and attributed to HDA (high density amorphous) and LDA (low density amorphous) states, respectively (Wilding and McMillan, 2001; Wilding *et al.*, 2002a,b; Nasikas *et al.*, 2011). The two glassy states were mechanically separated to determine their respective densities (3.72 and 3.58 g cm^{-3}), allowing the assignment of the HDA and LDA to the inclusions and the glass matrix, respectively (McMillan and Wilding, 2008). Note that the assignment is surprising since single HDA glass can be formed, suggesting that it is the stable amorphous form, and several studies indicate LDA inclusions in the HDA glass matrix (Florian *et al.*, 2001; Nasikas *et al.*, 2011). The two HDA-LDA states imply a density-driven phase separation that could underline a first-order liquid-liquid phase transition. However the occurrence of this polyamorphism has been strongly debated (Greaves *et al.*, 2008; Barnes *et al.*, 2009; Greaves *et al.*, 2009).

Fig. 9 (a) Photomicrograph of a $23\text{Y}_2\text{O}_3$ - $77\text{Al}_2\text{O}_3$ sample, showing sub-spherical glassy inclusions embedded within a glassy matrix. (b) Electron microprobe analysis for all elements (Y, Al, O) across a single inclusion. The lack of composition change at the inclusion-matrix interface indicates identical chemical compositions. Structural studies, using ^{27}Al and ^{89}Y NMR, Raman and diffraction, have been conducted mainly on $\text{Y}_2\text{O}_3\text{-Al}_2\text{O}_3$ and $\text{La}_2\text{O}_3\text{-Al}_2\text{O}_3$ glasses among $\text{RE}_2\text{O}_3\text{-Al}_2\text{O}_3$ glasses (Florian *et al.*, 2001; Wilding *et al.*, 2002a,b; Wilding and McMillan, 2002; McMillan *et al.*, 2003; Weber *et al.*, 2004; Tangeman *et al.*, 2004; Nasikas *et al.*, 2011; Watanabe *et al.*, 2020), supported by MD simulations (McMillan *et al.*, 2007; Du and René Corrales, 2007; Cristiglio *et al.*, 2007; Du *et al.*, 2009). Aluminum occurs predominantly in tetrahedral environment but, in La aluminate glasses, the population of $^{[4]}\text{Al}$ slightly increases with Al_2O_3 from 85% for 27 mol% La_2O_3 to 94% for 50 mol% La_2O_3 (Watanabe *et al.*, 2020), while the fraction of $^{[4]}\text{Al}$ is essentially composition independent in YA glasses and has low values between 61% (Watanabe *et al.*, 2020) and 69% (Tangeman *et al.*, 2004). High coordinated Al species are detected in all Y- and La-aluminate glasses with rather large fractions of $^{[5]}\text{Al}$ (24%–28%) and $^{[6]}\text{Al}$ (6%–11%) in YA glasses (Watanabe *et al.*, 2020; Tangeman *et al.*, 2004). ^{27}Al 3Q-MAS reveals the presence of two different $^{[5]}\text{Al}$ environments in a YA glass with 37.5 mol% Y_2O_3 , supporting a phase separation (Florian *et al.*, 2001) but this was not confirmed in further investigations (Tangeman *et al.*, 2004; Nasikas *et al.*, 2011). Diffraction results indicate an average CN of 7 oxygen atoms around La (Weber *et al.*, 2004), as confirmed by MD simulations (Du and René Corrales, 2007). The Y-O distance distribution is asymmetric with distorted six and seven-fold polyhedra ($^{[6]}\text{Y}$ and $^{[7]}\text{Y}$) (Wilding *et al.*, 2002a,b; McMillan *et al.*, 2003; Du *et al.*, 2009). Using ^{89}Y NMR, two distinct sites have been evidenced and interpreted as $^{[8]}\text{Y}$ and possibly $^{[9]}\text{Y}$ (Nasikas *et al.*, 2011). They were associated with different Y environments in the LDA and HDA (Nasikas *et al.*, 2011). An increase in the Y coordination number with increasing Al_2O_3 content emerges based on diffraction and NMR data (Weber *et al.*, 2004; Nasikas *et al.*, 2011). Several conclusions on the polyamorphic transition have been obtained from diffraction results (Fig. 10). Minor changes occur in the local Al environment (Wilding *et al.*, 2002a,b) contrary to the local Y environment that changes from $^{[7]}\text{Y}$ to $^{[8]}\text{Y}$ with the formation of LDA (Weber *et al.*, 2004). This is accompanied by a high-degree of medium range order in glasses with amorphous-amorphous separation, similar to that in La aluminate glasses (Wilding *et al.*, 2002a,b). These changes at medium range distance indicate specific packing among AlO_n and YO_n units as revealed by metal-metal distances (Wilding *et al.*, 2002a,b; McMillan *et al.*, 2003; Weber *et al.*, 2004). These modifications can be ascribed to a shift from corner to edge sharing between polyhedra as the Y coordination increases (Weber *et al.*, 2004). MD simulations confirm that changes in the Y-Y correlations is the main difference between HDA and LDA configurations (McMillan *et al.*, 2003). Furthermore, dynamic density fluctuations have been evidenced in MD simulations (McMillan *et al.*, 2007), confirming experimental indication of unmixing of high and low density liquids at the nanoscale that underlines a liquid-liquid phase transition (Greaves *et al.*, 2008, 2009).

Compared to conventional silicate glasses, RE aluminate glasses have high hardness, high elastic moduli, and high cracking resistance CR, depending on the RE^{3+} ionic radius, r_{RE} . Increasing r_{RE} yields a decrease in packing density, elastic moduli and hardness and an increase in CR (Rosales-Sosa *et al.*, 2018). The proposed mechanism underlying this high CR is the possibility for aluminum to adopt diverse coordination environments. This flexibility is higher than in silicate glasses, for which only SiO_4 tetrahedra are possible, and favors a stress release during plastic deformation. Large r_{RE} (e.g., for La) enhances the flexibility of the glass network compared to small r_{RE} (e.g., for Y). Indeed, Al in tetrahedral environment exists in large fractions in $\text{La}_2\text{O}_3\text{-Al}_2\text{O}_3$

Fig. 10 X-ray total pair-correlation functions for a single-HDA glass (AY25 = $25\text{Y}_2\text{O}_3\text{-}75\text{Al}_2\text{O}_3$) and a two-phase HDA-LDA glass (AY20 = $20\text{Y}_2\text{O}_3\text{-}80\text{Al}_2\text{O}_3$). The Al-O peak remains unchanged on transition from HDA to LDA. Conversely, there is an increase in the Y-O distance and in mid-range order (especially the peak ascribed to Y-Y correlations) in the HDA suggesting higher numbers of corner-shared $\text{AlO}_n\text{-YO}_n$ polyhedra and edge-shared $\text{YO}_n\text{-YO}_n$ polyhedra. glasses and these $^{[4]}\text{Al}$ are available to increase their oxygen CN under applied stress, whereas $^{[5]}\text{Al}$ and $^{[6]}\text{Al}$ species already exist in significant proportions in $\text{Y}_2\text{O}_3\text{-Al}_2\text{O}_3$ glasses so that a local Al change is difficult, associated with a high packing density that reduces densification ability.

Comparing RE^{3+} and M^{2+} aluminate glasses, Watanabe *et al.* (2020) have shown that above a packing density of $\sim 55\%$, the network cannot accommodate only AlO_4 units. The less efficiency of RE^{3+} cations compared to M^{2+} cations for charge compensation of $(\text{AlO}_4)^-$ tetrahedra is related to the high CFS of RE^{3+} cations. RE^{3+} cations attract oxygen atoms more strongly than M^{2+} cations, bringing AlO_4 polyhedra closer to each other and increasing the packing density. Ideally, each RE^{3+} should charge balance three AlO_4 tetrahedra, which is topologically difficult if corner-sharing is maintained.

$\text{Al}_2\text{O}_3\text{-SiO}_2$ Binary Glasses

Replacement of silicon by aluminum has been investigated in the $\text{Al}_2\text{O}_3\text{-SiO}_2$ (AS) binary system. Materials with high alumina content are considered for refractories and small amounts of Al_2O_3 help to homogenize the distribution of RE in optically active devices (Lægsgaard, 2002; Weber *et al.*, 2008). Alumina-rich AS glasses, particularly at the mullite composition, $3\text{Al}_2\text{O}_3\text{-2SiO}_2$, have remarkable high hardness and high indentation cracking resistance with an elastic modulus as high as 134 GPa (Rosales-Sosa *et al.*, 2016). The liquids along the $\text{Al}_2\text{O}_3\text{-SiO}_2$ join cover a wide range of viscosity-temperature behavior, from strong (SiO_2 -rich) to fragile with increasing Al_2O_3 contents (Wilding *et al.*, 2010). There is a wide metastable immiscibility gap in the AS binary, starting above 5 mol% Al_2O_3 and finishing below 60 mol% Al_2O_3 , i.e., near the mullite composition (Macdowell and Beall, 1969; Risbud and Pask, 1977; Risbud, 1982). Though homogeneous glasses are difficult to prepare due to high viscosities for undercooled melts and the tendency to phase separate, they can be prepared using fast-quenching techniques (contactless, flame-spraying, roller-quenching ...) or via a sol-gel route.

The structure of AS glasses was studied from SiO_2 containing Al_2O_3 impurities up to 67 mol% Al_2O_3 , mainly in relation to Al speciation. At very low Al_2O_3 contents, $^{[4]}\text{Al}$ is the most dominant species but distorted $^{[6]}\text{Al}$ and a minor amount of $^{[5]}\text{Al}$ is also present (Poe *et al.*, 1992; Sen and Stebbins, 1995; Sen and Youngman, 2004). The mechanisms of charge compensation for $(\text{AlO}_4)^-$ is still not clear. Oxygen triclusters (Lacy, 1963; Macdowell and Beall, 1969; Schmücker *et al.*, 1997; Schmücker and Schneider, 2002), O vacancies (Lægsgaard, 2002), interstitial Al atoms in the network (Day and Rindone, 1962; Lægsgaard, 2002) or three-coordinated Al ($^{[3]}\text{Al}$) (Brower, 1978, 1979) have been proposed. While the existence of O_{tri} is still debated due to the difficulties to have experimental signatures, computational simulations agree with their formation (Winkler *et al.*, 2004; Tossell and Horbach, 2005). The presence of O_{tri} induces a tightening and densification of the silicate network, increasing the glass stiffness. They have been invoked to favor phase separation and initiate crystallization (Macdowell and Beall, 1969; Schmücker and Schneider, 2002), though structural homogeneity has been suggested at molecular scales (Ando *et al.*, 2018). MD models have shown substantial fractions of $^{[3]}\text{Al}$, for instance $\sim 38\%$ at 5 mol% Al_2O_3 (Poe *et al.*, 1992) but limited experimental evidence for such species exist (Brower, 1978, 1979). Addition of Al_2O_3 results in the rapid disappearance of 3- and 4-membered rings and increases disorder (Okuno *et al.*, 2005; Ando *et al.*, 2018).

At higher Al_2O_3 content (>4 mol%), the three coexisting $^{[4,5,6]}\text{Al}$ species were observed in numerous experimental investigations with somewhat contradictory results (Morikawa *et al.*, 1982; Risbud *et al.*, 1987; Sato *et al.*, 1991; Poe *et al.*, 1992; Sen and Youngman, 2004; Okuno *et al.*, 2005; Weber *et al.*, 2008; Wilding *et al.*, 2010; Ren *et al.*, 2014). A peak at 30 ppm in ^{27}Al NMR spectra, usually assigned to $^{[5]}\text{Al}$, is sometimes attributed to a distorted triclustered $^{[4]}\text{Al}$ configuration (Schmücker and Schneider, 1996, 2002). However, the main observed trend is that $^{[4,5]}\text{Al}$ are the dominant species and $^{[6]}\text{Al}$ persists but in small fractions. A recent ^{27}Al NMR investigation concludes with the absence of significant compositional dependence, even in phase separated glasses, up to 28 mol% Al_2O_3 , and only Si-O- $^{[4,5]}\text{Al}$ and Si-O-Si linkages are detected with no Al-O-Al linkages (Sen and Youngman, 2004). The concentration of $^{[5,6]}\text{Al}$ species increases upon further addition of Al_2O_3 (up to 60 mol% Al_2O_3) (Risbud *et al.*, 1987) and $^{[5]}\text{Al}$ becomes the predominant species (Weber *et al.*, 2008; Hoang, 2007). The exact Al speciation appears to depend on the synthesis conditions and quenching rates (Sato *et al.*, 1991; Poe *et al.*, 1992; Okuno *et al.*, 2005; Ren *et al.*, 2014). For instance, at a slow quench rate, there is no $^{[5]}\text{Al}$ and only the presence of $^{[4]}\text{Al}$ and $^{[6]}\text{Al}$ species is observed (Sato *et al.*, 1991; Poe *et al.*, 1992). MD simulations indicate large fractions of $^{[3]}\text{O}$ (and not O_{tri} as inaccurately stated in the papers) that are bonded to two edge-shared AlO_n polyhedra and an additional corner-shared AlO_4 or SiO_4 tetrahedron (Winkler *et al.*, 2004; Pfeleiderer *et al.*, 2006; Hoang, 2007). From diffraction data, an average low Al-O-T angle of 125° has also been interpreted as edge-shared AlO_n polyhedra in addition to corner-shared units (Weber *et al.*, 2008). Such a configuration indicates a locally dense region and implies Al clustering that could prefigure phase separation. Proximity between all $^{[4,5,6]}\text{Al}$ units has been confirmed by advanced NMR techniques (Ren *et al.*, 2014). As the packing density increases with addition of Al_2O_3 , the elastic moduli and Vickers hardness increase. The improved elastic properties are probably due to the flexibility for Al to adapt its environment to stresses (Rosales-Sosa *et al.*, 2016). MD simulations indicate that indentation results from a shear deformation process at high Al_2O_3 content (Luo *et al.*, 2016). The increasing glass ductility with increasing Al_2O_3 content is caused by a high proportion of high-coordinated Al that prevents the formation of defects acting as weak spots during deformation.

Alkali Aluminosilicate Glasses

Alkali-bearing aluminosilicate glasses have wide applications, such as chemically strengthened cover glasses or precursors for glass-ceramics. $\text{Na}_2\text{O-Al}_2\text{O}_3\text{-SiO}_2$ (NAS) glasses have attracted attention due to non-monotonic changes in physical properties, such as refractive index, density, viscosity and electrical conductivity (Day and Rindone, 1962; Riebling, 1966; Toplis *et al.*, 1997a,b).

Fig. 11 Experimental viscosities at 1869 K in Na-AS glasses with different SiO₂ contents as a function of Na/(Na + Al). Data from Toplis, M.J., Dingwell, D.B., Lenci, T., 1997b. Peraluminous viscosity maxima in Na₂O-Al₂O₃-SiO₂ liquids: The role of triclusters in tectosilicate melts. *Geochimica et Cosmochimica Acta* 61, 2605–2612.

Viscosity measurements have shown a particularly interesting behavior (Fig. 11) (Riebling, 1966; Toplis *et al.*, 1997a,b): at a constant SiO₂ content, viscosities increase when Al substitutes for Na (ratio $R = \text{Na}/\text{Al} < 1$) with a maximum near $R = 1$ or slightly in the peraluminous region ($R = 1.2$) and then decreases slightly in the peraluminous region ($R > 1$). A similar behavior is also reported for Li₂O-Al₂O₃-SiO₂ (LAS) glasses (Shelby, 1978). In the peralkaline region, the Al environment has been confirmed to be only tetrahedral by ²⁷Al NMR experiments (Lee and Stebbins, 2000b; Allwardt *et al.*, 2005b), consisting of Q⁴ species and conferring a pure network forming role on Al (Gambuzzi *et al.*, 2014). Only ¹⁴Al is also detected in KAS glasses (Thompson and Stebbins, 2011; Le Losq *et al.*, 2017). The extremum in viscosity and its occurrence slightly in the peraluminous region has been strongly debated. This anomaly has not yet been truly understood since it can be attributed to the formation of O_{tri} or Al in high coordination states (Lacy, 1963; Riebling, 1966; Toplis *et al.*, 1997b).

Experiments have failed to evidence the presence of O_{tri} because either this moiety in glasses does not exist or is not present in significant amounts or current experiments are unable to identify it. For instance, the ¹⁷O NMR signature of O_{tri} is predicted to fall in the range of chemical shifts for regular BO (Kubicki and Toplis, 2002). Alternatively, MD simulations usually have significant contents of O_{tri} (typically 1%–10%) (Xiang *et al.*, 2013). The identification of O_{tri} can be an artifact due to fast quenching rates in simulations and, as such, MD models are more representative of a high temperature structure similar to that prevailing in viscosity measurements.

An increase in ¹⁵Al concentration would contribute to a decrease in viscosity (Toplis and Dingwell, 2004) and five-fold coordinated species are considered to be involved in the viscous flow of the network, promoting the exchange of T-O-T links (Farnan and Stebbins, 1994; Stebbins and Farnan, 1992). Their influence is expected to be more important for compositions with very polymerized networks, such as silica or albite, NaAlSi₃O₈, melts.

The presence of ¹⁴Al-O-¹⁴Al linkages is negligible in the peralkaline region but tends to increase for compositions close to $R = 1$ (Lee and Stebbins, 1999, 2009). The values of glass transition temperatures (T_g) steeply increase near $R = 1$, which is explained as changes of the Si speciation from Q³_{Si}(0Al) to Q⁴_{Si}(*m*Al) units based on Raman spectroscopy (Le Losq *et al.*, 2014). In the peraluminous region, the fraction of ¹⁵Al increases and the structure has been considered to be more constrained than for tectosilicate compositions as a result of ring statistics close to a “perfect” six-membered ring distribution (Le Losq *et al.*, 2014). It was concluded that the presence of ¹⁵Al in peraluminous glasses strongly impacts the rheologic and thermodynamic properties.

Li₂O-Al₂O₃-SiO₂ (LAS) glasses have considerable importance as they are the precursors for most of commercialized glass-ceramics. They have also been considered due to the fast Li mobility and the potential development of solid-state electrolytes for ionic batteries (Pechenik *et al.*, 1986, 1988; Greaves and Ngai, 1995a,b; Ross *et al.*, 2015). Similar observations on the conductivity properties were obtained for LAS and NAS (Li and Garofalini, 2004; Zirl and Garofalini, 1990). The initial introduction of Al₂O₃ blocks the alkali channels existing in the MRN model, increasing the activation energy for diffusion (Greaves and Ngai, 1995a). With further addition of Al₂O₃, a large fraction of alkalis changes their structural role, from modifying associated with NBOs, to charge balancing near (AlO₄)[−] units, associated with BOs in

Fig. 12 Variation of the activation energy of alkali diffusion as determined by MD simulations in Na and Li AS glasses as a function of Al/M content ($M = \text{Li}$ or Na). Curves are only guides for the eye. Data from Zirl, D.M., Garofalini, S.H., 1990. Structure of sodium aluminosilicate glasses. *Journal of the American Ceramic Society* 73, 2848–2856, and Li, W., Garofalini, S.H., 2004. Molecular dynamics simulation of lithium diffusion in $\text{Li}_2\text{O}-\text{Al}_2\text{O}_3-\text{SiO}_2$ glasses. *Solid State Ionics* 166, 365–373.

$\text{Si}-\text{BO}-[4]\text{Al}$ bonds. Alkalis become loosely bounded due to large $M^+-\text{BO}$ bond lengths and small $M^+-\text{BO}$ binding energies compared to $M^+-\text{NBO}$ bonds. As a result, the activation energy decreases as $M^+-\text{BO}$ bonds are formed and is the smallest for $M^+/\text{Al} = 1$ (Fig. 12) (Li and Garofalini, 2004; Zirl and Garofalini, 1990). The formation of $[5,6]\text{Al}$ species for $M^+/\text{Al} < 1$ decreases the activation energy, following a reduction of the free volume. Li atoms are found in distorted tetrahedral sites that share edges with TO_4 tetrahedra (Cormier *et al.*, 1998, 2001). Due to Si/Al ordering, AlO_4 units are homogeneously distributed in the network, explaining large inter-alkali distances in AS glasses (Cormier *et al.*, 1998, 2001; Greaves and Ngai, 1995a). The proposed mechanism for alkali diffusion is a hopping process from a $(\text{AlO}_4)^-$ unit to another $(\text{AlO}_4)^-$ unit, provided by a higher free volume than for crystalline counterparts.

Alkaline-Earth Aluminosilicate Glasses

Alkaline-earth aluminosilicate glasses exhibit interesting optical and mechanical properties and form the basis of a plethora of commercial glasses from nuclear, domestic and industrial waste storage, slags, cements, fibers, and industrial glasses.

GFA in the $\text{CaO}-\text{Al}_2\text{O}_3-\text{SiO}_2$ (CAS) system is remarkable since low- SiO_2 glasses can be formed, allowing compositions to be studied along the almost complete $R = \text{CaO}/\text{Al}_2\text{O}_3$ joins. Strong non-linear behavior has been observed for T_g (Higby *et al.*, 1990; Cormier *et al.*, 2005): a minimum at 30–40 mol% SiO_2 along the join $R = \text{Ca}/2\text{Al} = 1$ and at 50–60 mol% SiO_2 along the joins $R = 1.57$ and 3; for these two latter, an additional maximum at 10–20 mol% SiO_2 is also observed. These observations have motivated numerous studies, especially on the connectivity of the tetrahedral aluminosilicate network. A large structure database exists for CAS based on various experimental and modeling techniques (Murdoch *et al.*, 1985; Engelhardt *et al.*, 1985; Merzbacher and White, 1991; Himmel *et al.*, 1991; Stebbins and Xu, 1997; Petkov *et al.*, 2000; Cormier *et al.*, 2000b; Lee and Stebbins, 2000b; Allwardt *et al.*, 2003; Stamboulis *et al.*, 2004; Neuville *et al.*, 2006; Lee and Stebbins, 2006; Neuville *et al.*, 2007; Moesgaard *et al.*, 2010; Thompson and Stebbins, 2011; Tandia *et al.*, 2011; Jakse *et al.*, 2012; Zheng *et al.*, 2012; Thompson and Stebbins, 2012; Bouhadja *et al.*, 2014) to determine the topological disorder, coordination numbers, bond-angle distribution, linkages between polyhedra and fulfillment of the aluminum avoidance principle. From these investigations, a general structural picture emerges that changes with R and SiO_2 content. Near pure SiO_2 , the glass structure is composed of a fully connected network of corner-shared TO_4 tetrahedra and the addition of CaO progressively depolymerizes the network. Al^{3+} cations preferentially replace Si^{4+} cations in tetrahedral positions with Ca^{2+} charge balancing two $(\text{AlO}_4)^-$ tetrahedra. Additionally, Al atoms prefer to occupy fully polymerized Q^4 sites and NBOs are almost entirely associated with Si atoms (Engelhardt *et al.*, 1985; Allwardt *et al.*, 2003). High coordinated Al polyhedra are expected only for insufficient modifier contents. However, a substantial fraction of $[5]\text{Al}$ species and minor amounts of $[6]\text{Al}$ species are present throughout the CAS ternary system, except at high SiO_2 content and for the low silica percalcic region ($\text{SiO}_2 < 16$ mol%) (Fig. 13). The maximum $[5,6]\text{Al}$ fraction is observed near 40 mol% SiO_2 for all joins in the percalcic region with a maximum of 7%–8% $[5]\text{Al}$ (Neuville *et al.*, 2006, 2007). The presence of these high-coordinated species implies higher amounts of NBOs and $[3]\text{O}$ and non-negligible fractions of NBOs are observed along the charge-balanced join (Stebbins and Xu, 1997; Lee and Stebbins, 2006; Stebbins *et al.*, 2008). Ca is acting both as a modifier and as a charge compensator and is localized in distorted sites with 6–7 oxygen neighbors, within interstitial spaces of the tetrahedral network (Cormier *et al.*, 2003; Neuville *et al.*, 2004a; Mongalo *et al.*, 2016). The Al avoidance principle is violated and a quasi-heterogeneous distribution of Al as second neighbors around Si was

Fig. 13 Comparison of the ^{151}Al fraction in tecto-aluminosilicate glasses containing alkaline-earth cations (MAS: Mg^{2+} ; CAS: Ca^{2+} ; SAS: Sr^{2+} ; BAS: Ba^{2+}) (a) as a function of the SiO_2 content (curves are guides for the eye) or (b) as a function of the ratio $\text{Al}_2\text{O}_3/\text{MO}$. proposed (Moesgaard *et al.*, 2010). This model suggests the existence of depolymerized Si-NBO-Ca regions and highly polymerized regions of alternating SiO_4 -(1/2Ca) AlO_4 units. MD simulations suggest spatial correlation between ^{151}Al and ^{13}O within small 2- and 3-fold membered rings (Benoit *et al.*, 2005; Agnello *et al.*, 2019; Atila *et al.*, 2019). As the SiO_2 content decreases below 40 mol%, Al atoms enter depolymerized Q^3 and Q^2 units and the number of NBOs per SiO_4 tetrahedron decreases (Neuville *et al.*, 2006, 2007; Bouhadja *et al.*, 2014), forming a highly depolymerized network. The lower network connectivity of Al_2O_3 -rich glasses increases the reactivity, which is crucial for developing supplementary cementitious materials (Nie *et al.*, 2020). The presence of NBOs and their distribution on Si and Al units are correlated with the evolution of T_g and the fragility behavior of the corresponding melts. For peraluminous glasses, large proportions of ^{151}Al exceeding 20% are observed but these compositions have been little investigated (Fig. 13(b)) (Neuville *et al.*, 2006, 2007). It has been suggested that non negligible fractions of NBOs are still present within the peraluminous region (Mysen and Toplis, 2007; Thompson and Stebbins, 2011).

The $\text{MgO-Al}_2\text{O}_3\text{-SiO}_2$ (MAS) system has a reduced GFA but the glass structure follows the general trends observed for CAS (McMillan and Kirkpatrick, 1992; Toplis *et al.*, 2000). The main difference from their CAS counterparts is that higher fractions of $^{15,61}\text{Al}$ species are detected in MAS glasses (Fig. 13) (Neuville *et al.*, 2008). Divalent cations have thus a lower ability to stabilize ^{14}Al than monovalent alkali cations. The average CN for Mg is close to 5 with a distribution between 4-, 5- and 6-fold coordinated sites (Guignard and Cormier, 2008; Mongalo *et al.*, 2016). Therefore, owing to its small size and its localization in interstitial sites of the aluminosilicate network, Mg^{2+} cations perturb the network more severely than Ca^{2+} cations (Navrotsky *et al.*, 1982; Roy and Navrotsky, 1984) and the network distortion can result in the formation of high-coordinated Al. Furthermore, the high CFS for Mg^{2+} favors the stabilization of more concentrated negative charges on NBOs or partially charged BOs involved in $^{14}\text{Al}\text{-O-}^{14}\text{Al}$ linkages. These different influences of Mg^{2+} and Ca^{2+} on the glass structure impact the macroscopic properties (density, Young's modulus, Vickers hardness, coefficient of thermal expansion, liquid fragility) (Smedskjaer *et al.*, 2013).

In mixed Ca-Mg aluminosilicate glasses (CMAS), the fraction of ^{151}Al species increases with MgO content and is less affected by the Si/Al or M^{2+}/Al substitutions (Lee *et al.*, 2005; Neuville *et al.*, 2008; Kelsey *et al.*, 2008; Nie *et al.*, 2020). The network polymerization depends mainly on the content of alkaline-earth ions and to a much lesser extent on the Al/Si and Mg/Ca substitutions (Nie *et al.*, 2020). The degree of Si-Al disorder (presence of $^{14}\text{Al}\text{-O-}^{14}\text{Al}$) increases with the presence of Mg^{2+} cations and increasing Al/Si ratio (Lee *et al.*, 2005; Kelsey *et al.*, 2008). NBOs have more Mg^{2+} cations in their environment than Ca^{2+} cations. These latter cations are thus more associated with Al-O-Si linkages and slightly more available than Mg to charge balance $(\text{AlO}_4)^-$ units (Kelsey *et al.*, 2008). This result is consistent with MD simulations indicating that more Ca ions are acting as charge compensator than Mg (Allu *et al.*, 2018; Ganisetti *et al.*, 2019). The non-random distribution of framework and non-framework cations supports the EMRN model implying an heterogeneous network (Fig. 4).

Mechanical properties have been explored in CAS and MAS glasses (Smedskjaer *et al.*, 2012; Veit and Rüssel, 2016), showing that increasing Al_2O_3 content provokes higher atomic packing density, responsible for higher values of Poisson ratio and that CFS has a high impact on elastic moduli. In CAS and MAS glasses, hardness shows an "anomalous" behavior with a minimum (at ~ 85 mol% SiO_2 for CAS and ~ 70 mol% SiO_2 for MAS) and has higher values for MAS over CAS glasses (Lamberson, 2016). As the hardness correlated with the proportion of $^{151}\text{Al} + ^{161}\text{Al}$ ($R^2 = 0.9\text{--}0.91$), Lamberson (2016) proposed that the presence of

$^{[5,6]}\text{Al}$ prevents the Ca-O bond breaking and reforming, this latter mechanism causing NBO motion and creating shear deformation. Indeed, NBOs are tightly held by $^{[5,6]}\text{Al}$ since edged-shared $^{[5,6]}\text{Al}$ - $^{[4]}\text{T}$ bonds are stronger than $^{[4]}\text{T}$ - $^{[4]}\text{T}$ ones. $^{[5,6]}\text{Al}$ ties up the structure and is beneficial for better crosslinking network fragments. Therefore, $^{[5,6]}\text{Al}$ can prevent or slow down plastic deformation, and consequently hardness is increased. In addition to larger amounts of $^{[5,6]}\text{Al}$ in MAS glasses, Mg-NBO bonds are stronger than Ca-NBO bonds and NBOs have thereby a lower ability to move in a MAS network over a CAS network, such that shear deformation is further inhibited. The different hardness behavior between the two alkaline earth cations is related to both higher proportion of $^{[5,6]}\text{Al}$ and stronger Mg-NBO bonds. The fraction of $^{[5,6]}\text{Al}$ has then a prominent role in controlling mechanical properties (shear deformation and hardness) of tectosilicate glasses with $\text{SiO}_2 < 85$ mol%.

Other alkaline-earth AS glasses have been investigated less though the structure of Sr and Ba AS glasses have been explored (Thompson and Stebbins, 2012; Novikov *et al.*, 2017; Charpentier *et al.*, 2018). The substitution of Si by SrAl_2O_4 favors the formation of small-size rings. A CN for Sr near 6 was determined using an advanced diffraction investigation (Cormier *et al.*, 1999), while a CN of 9 was proposed based on a crude fingerprint XANES approach (Novikov *et al.*, 2017) and MD simulations indicate a broad distribution with maximum at ~ 7 –8 (Charpentier *et al.*, 2018). The proportion of $^{[5]}\text{Al}$ is smaller ($< 5\%$) for Sr^{2+} and Ba^{2+} than for Ca^{2+} and Mg^{2+} (Fig. 13), thus following the trend $\text{Ba} < \text{Sr} < \text{Ca} < \text{Mg}$ that suggests an important size effect for these divalent cations (Thompson and Stebbins, 2012).

Rare-Earth Aluminosilicate Glasses

Glass formation (Makishima *et al.*, 1978, 1982; Hyatt and Day, 1987; Shelby, 1994; Clayden *et al.*, 1999; Iftekhar *et al.*, 2011; Pahari *et al.*, 2012) and the thermodynamic behavior (Zhang and Navrotsky, 2003, 2004) have been investigated in RE-based aluminosilicate glasses (RE-AS). The presence of trivalent RE cations (Sc^{3+} , Y^{3+} and lanthanides) in AS glasses leads to useful physico-chemical and mechanical properties: high refractive index, hardness and elastic modulus, low corrosion. RE-AS glasses are refractory with high T_g values ($T_g > 840^\circ\text{C}$) and high chemical stability (Hyatt and Day, 1987; Shelby and Kohli, 1990; Tanabe *et al.*, 1992; Johnson *et al.*, 2005). Most glass properties depend on the cation mass and CFS with the noticeable exception of Sc-bearing glasses that show anomalously low T_g values, possibly related to Sc clustering (Iftekhar *et al.*, 2011). The density, refractive index, thermal expansion coefficient, microhardness, electrical resistivity all increase with the addition of RE oxides (Makishima *et al.*, 1978; Shelby, 1994; Johnson *et al.*, 2005; Pahari *et al.*, 2012). Decreasing the ionic size increases the elastic moduli and the thermal expansion coefficient (Shelby and Kohli, 1990; Inaba *et al.*, 2000; Tanabe *et al.*, 1992). Owing to high refractive indices, they exhibit excellent optical properties and they can be used in technological applications, such as components in lenses, optical amplifiers, laser hosts, fiber optics. They have also been considered as potential matrices for storage of radioactive wastes (Bardez *et al.*, 2005; Loiseau and Caurant, 2010; Kidari *et al.*, 2012) and explored in radiotherapy for in situ cancer treatment (Christie and Tilocca, 2010a,b). Addition of Al_2O_3 is beneficial to obtain homogeneous glasses with high contents of uniformly dispersed RE^{3+} cations.

RE-AS glasses have pronounced configurational and chemical disorder compared to alkaline or alkaline-earth AS glasses. Whereas tetrahedral coordination is still dominant, large amounts of $^{[5,6]}\text{Al}$ populations prevail throughout the entire range of RE-AS glass forming regions (Jaworski *et al.*, 2015; Schaller and Stebbins, 1998; Florian *et al.*, 2007; Iftekhar *et al.*, 2011; Jaworski *et al.*, 2012; Iftekhar *et al.*, 2012; Pahari *et al.*, 2012; Okhotnikov *et al.*, 2013), with larger amounts compared to mono/divalent cations. The relative amounts of $^{[5,6]}\text{Al}$ grow with decreasing SiO_2 content (Florian *et al.*, 2007; Iftekhar *et al.*, 2012; Jaworski *et al.*, 2012) and increasing CFS (Schaller and Stebbins, 1998; Florian *et al.*, 2007; Iftekhar *et al.*, 2011; Jaworski *et al.*, 2012; Pahari *et al.*, 2012) and depends on the RE/Al ratio:

- (1) When $\text{RE}/\text{Al} < 3$, not enough RE^{3+} cations are present to ensure charge neutralization of $(\text{AlO}_4)^-$ groups and the highest amounts of $^{[5]}\text{Al}$ (35%) and $^{[6]}\text{Al}$ (5%) are observed (Schaller and Stebbins, 1998; Florian *et al.*, 2007; Pahari *et al.*, 2012);
- (2) When $\text{RE}/\text{Al} \geq 3$, $^{[4]}\text{Al}$ is predominant with small fractions of $^{[5,6]}\text{Al}$ and RE cations act as modifiers, depolymerizing the network with the formation of NBOs preferentially localized on SiO_4 tetrahedra (Lin *et al.*, 1996; Schaller and Stebbins, 1998).

The higher coordinated $^{[5,6]}\text{Al}$ species imply a significant cross-linked AS network that is suggested to explain the enhanced Vickers hardness with increasing CFS (Iftekhar *et al.*, 2012; Svensson and Edén, 2013). A pronounced Al/Si atomic disorder (violation of Al avoidance principle) is observed based on NMR results (Iftekhar *et al.*, 2009; Jaworski *et al.*, 2012), as well as MD simulations (Jaworski *et al.*, 2012; Okhotnikov *et al.*, 2013). Even for SiO_2 -rich glasses, in contrast to mono/divalent cations, NBOs directly connected with $^{[6]}\text{Al}$ were experimentally observed using ^{17}O MAS NMR spectroscopy (Jaworski *et al.*, 2015), an observation corroborated by MD simulations (Okhotnikov *et al.*, 2013).

X-ray absorption spectroscopy (XAS) and NMR were used to determine CNs and infer constraints on the cation clustering by leveraging on MD simulations (Ponader and Brown, 1989; Sen and Stebbins, 1995; Du, 2009; Christie and Tilocca, 2010a,b; Jaworski *et al.*, 2012; Iftekhar *et al.*, 2012; Pahari *et al.*, 2012; Okhotnikov *et al.*, 2013). The main factors influencing the local RE environment in glasses have been identified (Ponader and Brown, 1989; Wang *et al.*, 1993; Okhotnikov *et al.*, 2013): as the RE ionic radius increases, the RE-O distances and CNs increase while the sites occupied by RE^{3+} cations become less regular. Lanthanum behaves slightly differently with more regular sites and is considered to be centered in a “cage” formed by the rings of TO_4 tetrahedra. Due to a large ionic radius ratio ($r_{\text{RE}}/r_{\text{O}} > 0.732$) and a strong ionicity of RE-O bonds (Tanabe *et al.*, 1992), CNs for RE^{3+} are larger than for Al^{3+} . Octahedral coordination is the most probable one for the smallest ions (Sc, Lu) and high CNs (7) are observed for large RE cations (La, Y). MD simulations indicate a large distribution of CNs in the range from 4 to 8, with 4-fold and 8-fold coordination being significant only for Sc and La, respectively.

Fig. 14 Vickers hardness, H_V , as a function of the average Al coordination, $\bar{Z}_{Al}$, for various RE aluminosilicate glasses. The solid line is the best-fit ($H_V = -24 + 7.7\bar{Z}_{Al}$; $R^2 = 0.92$) revealing a strong property/structure correlation. Reprinted with permission from Svensson, B., Edén, M., 2013. Structural rationalization of the microhardness trends of rare-earth aluminosilicate glasses: interplay between the RE^{3+} field-strength and the aluminum coordinations. *Journal of Non-Crystalline Solids* 378, 163–167. doi:10.1016/j.jnoncrysol.2013.06.013.

Investigations have established relationships between mechanical properties and structural parameters (Iftekhar *et al.*, 2012; Svensson and Edén, 2013). The CFS or the network connectivity increase with hardness values. However, ideas have emerged that RE ions impact microhardness indirectly through the formation of $^{[5,6]}Al$. Fig. 14 shows an excellent correlation ($R^2 = 0.92$) between Vickers hardness, H_V , and the average Al coordination number for many RE-AS glasses. Therefore, increasing amounts of $^{[5,6]}Al$, originating from the high CFS of RE^{3+} cations, primarily account for the enhanced microhardness. AlO_5 and AlO_6 (and ReO_n) polyhedra are expected to connect different network fragments, yielding a more compact and stiffer network that favors high hardness.

Complex Aluminosilicate Glasses

Chemically complex aluminosilicate glasses are numerous and two aspects have been explored particularly: (1) mixing of different modifiers and (2) mixing of different framework cations (mainly, B^{3+} or P^{5+}).

When more than one type of non-network forming cation is present in AS glasses, the CFS affects their relative distribution between a modifying or charge balancing position. This type of disorder is mirrored in the preference of NBOs and BOs to be bonded to specific cations and in the formation of $^{[5,6]}Al$. Mixing of non-framework cations has been explored in AS glasses with Ca-Mg (Neuvill *et al.*, 2008; Kelsey *et al.*, 2008; Park and Lee, 2012; Smedskjaer *et al.*, 2013; Allu *et al.*, 2018; Ganisetti *et al.*, 2019), Ca-Na (Cormier and Neuvill, 2004; Lee and Sung, 2008; Gambuzzi *et al.*, 2014; Sukenaga *et al.*, 2017), Na-K (Le Losq and Neuvill, 2013; Le Losq *et al.*, 2017), Na-Mg (Park and Lee, 2018), Ca-Mg-Na (Smedskjaer *et al.*, 2013; Kjeldsen *et al.*, 2013; Park and Lee, 2014; Bechgaard *et al.*, 2017). In presence of alkalis and alkaline-earths, NBOs prefer to have proximity towards M^{2+} cations that preferentially play a role of network modifier, whereas BOs are more associated with M^+ cations that act as charge balancing cations in, typically, Si-BO- $^{[4]}Al$ environments. For Ca/Mg mixing, NBOs tend to have a Mg-rich environment, whereas Ca has a greater propensity to be associated with BOs. The non-randomness in the partitioning of non-framework cations around BOs and NBOs is explained by the CFS: higher CFS ($CFS_{M^{2+}} > CFS_{M^+}$ and $CFS_{Mg^{2+}} > CFS_{Ca^{2+}}$) favors proximity of cations to NBOs. However, in a $CaMgSi_2O_6$ - $CaAl_2SiO_6$ join, ^{17}O NMR reveals a Ca-NBO-Si peak, suggesting a preferential bonding of NBOs with Ca and/or a potential unmixing of Ca and Mg (Park and Lee, 2012). If the separation between polymerized regions and channels exists (EMRN model, Fig. 4), Na^+ cations will be preferentially localized in the polymerized Al/Si regions close to $^{[4]}Al$ to ensure charge compensation, while M^{2+} cations will be in channels associated with NBOs in depolymerized Q_{Si}^n species (Gambuzzi *et al.*, 2014; Sukenaga *et al.*, 2017). A major outcome of these studies is an increasing amount of $^{[5]}Al$ with CFS. For instance, the fraction of $^{[5]}Al$ increases from $\sim 5\%$ to $\sim 20\%$ as Ca is substituted by Mg, emphasizing the lower ability of Mg^{2+} to stabilize $^{[4]}Al$ (Neuvill *et al.*, 2008; Kelsey *et al.*, 2008).

The degree of Al/B mixing in boroaluminosilicate or boroaluminate glasses plays an essential role in controlling major physical properties such as chemical durability, phase separation, mechanical strength or crystallization behavior (Du *et al.*, 2000; Du and Stebbins, 2005a,b). The presence of B_2O_3 creates complex competition for M^{n+} cations for charge compensation of $(AlO_4)^-$ or $(BO_4)^-$ tetrahedra (El-Damrawi *et al.*, 1993; Chan *et al.*, 1999; Cormier *et al.*, 2000a; Yamashita *et al.*, 2003; Smedskjaer *et al.*, 2014). M^{n+} cations are firstly consumed to charge stabilize $(AlO_4)^-$ units, limiting the formation of higher Al coordination states. The excess M^{n+} cations are used to convert boron from trigonal (BO_3) to tetrahedral (BO_4) configurations. The proportion of BO_4 units, determined by the ratio $N_4 = BO_4/(BO_4 + BO_3)$, is then lower in boroaluminosilicate glasses compared to borosilicate counterparts. N_4 values increase with decreasing Al_2O_3 content and a maximum value, $N_{4(max)}$, is reached at $R' = ([Na_2O] - [Al_2O_3])/[B_2O_3] = 1$. When $N_4 < N_{4(max)}$ and $M^{n+}/nAl > 1$, NBOs on silicon can also be created but preferential formation of Q_{Si}^3 over BO_4 is observed depending on the M^{n+} cation type (Yamashita *et al.*, 2003). Fig. 15 represents the reactivity of M_nO with

Fig. 15 Relation between the fraction of BO_4 and the fraction of Q_3^{Si} for $0.139 \text{ M}^{\text{n}+}\text{O} - 0.673 \text{ SiO}_2 - (0.188-x) \text{ Al}_2\text{O}_3 - x\text{B}_2\text{O}_3$ ($\text{M}^{\text{n}+} = \text{Na}^+, \text{K}^+, \text{Mg}^{2+}, \text{Ca}^{2+}, \text{Sr}^{2+}$ and Ba^{2+}) glasses. Data from Yamashita, H., Inoue, K., Nakajin, T., Inoue, H., Maekawa, T., 2003. Nuclear magnetic resonance studies of $0.139\text{MO} \cdot 0.673\text{SiO}_2 \cdot (0.188 - x)\text{Al}_2\text{O}_3 \cdot x\text{B}_2\text{O}_3$ ($\text{M} = \text{Mg}, \text{Ca}, \text{Sr}$ and Ba , $\text{M}' = \text{Na}$ and K) glasses. *Journal of Non-Crystalline Solids* 331, 128–136. doi:10.1016/j.jnoncrysol.2003.08.086.

B_2O_3 and SiO_2 , showing that formation of Q_3^{Si} species is favored (and formation of BO_4 is disfavored) in the order $\text{Mg} > \text{Ca} > \text{Sr} > \text{Ba} > \text{Na} > \text{K}$. For compositions with $\text{M}^{\text{n}+}/\text{nAl} < 1$, N_4 values are expected to be equal to zero.

Non-zero population of high-coordinated Al sites are observed in borocaluminosilicate glasses with $\text{Na}/\text{Al} < 1$ (Smedskjaer *et al.*, 2014) or in presence of alkaline-earth cations (Bunker *et al.*, 1991; Baltisberger *et al.*, 1996; Chan *et al.*, 1999; Du and Stebbins, 2005a; Wu and Stebbins, 2009).

Using NMR spectroscopy (Chan *et al.*, 1999; Du and Stebbins, 2005a,b; Angeli *et al.*, 2001), the various structural linkages between AlO_4 , SiO_4 , BO_3 or BO_4 can be identified. $^{[4]}\text{Al}-\text{O}-^{[4]}\text{Al}$, $^{[4]}\text{Al}-\text{O}-^{[4]}\text{B}$ and $^{[4]}\text{B}-\text{O}-^{[4]}\text{B}$ interactions are disfavored (4–4 avoidance) and depend strongly on the composition and the type of cation $\text{M}^{\text{n}+}$. In $\text{B}_2\text{O}_3\text{-Al}_2\text{O}_3\text{-(SiO}_2)$ glasses, strong chemical ordering (4–4 avoidance) is respected with K or Na, whereas a trend toward random mixing is observed with Mg or Ca. High Al and/or low $\text{M}^{\text{n}+}$ contents favor obedience to 4–4 avoidance. In addition to lowering N_4 values by the formation of $^{[4]}\text{Al}$, the addition of Al lowers $\text{N}_{4(\text{max})}$ due to the 4–4 avoidance between $^{[4]}\text{B}$ and $^{[4]}\text{Al}$ (Du and Stebbins, 2005a). $\text{N}_{4(\text{max})}$ values are also higher for higher SiO_2 content since Si atoms limit the possibility of $^{[4]}\text{B}-\text{O}-^{[4]}\text{Al}$ linkages and allow a higher fraction of $^{[4]}\text{B}$. In borocaluminosilicate glasses (Chan *et al.*, 1999; Wang and Stebbins, 2004; Du and Stebbins, 2005b), $^{[6]}\text{Al}$ units interact with the dominant BO_3 sites without forming Al enriched regions or Al-O-Al linkages. $^{[4]}\text{Al}-\text{O}-^{[3]}\text{B}$ linkages are more probable than $^{[4]}\text{Al}-\text{O}-^{[4]}\text{B}$ one and they are energetically more stable than $^{[4]}\text{B}-\text{O}-^{[4]}\text{B}$ and $^{[4]}\text{Al}-\text{O}-^{[4]}\text{Al}$ ones. $^{[4]}\text{B}$ interacts preferentially with $^{[5,6]}\text{Al}$ rather than $^{[4]}\text{Al}$, suggesting that $^{[5,6]}\text{Al}$ species are stabilizing $^{[4]}\text{B}$.

Introduction

Borosilicate glasses are a family of oxide glasses, which are composed of two kinds of network formers, SiO_2 and B_2O_3 , and network modifiers such as alkali and alkaline oxides. A small amount of intermediate oxides such as Al_2O_3 and other oxides are often included in borosilicate glasses. They are one of the most useful inorganic glass systems, since they are applied in many applications such as health devices, pharmaceutical bottles, nuclear waste immobilization, electronics, lighting devices, cookware, optics, and fiber reinforced composites. These wide applications are attributed to their superior properties, e.g., low thermal expansion coefficient, high electrical resistivity, high optical transparency and low dispersion, and excellent chemical, thermal and mechanical durability. These properties allow borosilicate glass to play a crucial role in wet chemistry laboratories, as beakers, bottles, tubes and reaction vessels are made from this type of glass.

A striking feature of borosilicate glasses is their strong tendency to phase separation, especially when alkali ions are present in the glass. By taking advantage of phase separation, the high silica containing (up to 99 wt%) glass, so called Vycor[®] glass, was invented by Corning in 1939, and has been used in a wide range of applications from laboratory to early spacecraft viewing ports. Vycor[®] features excellent thermal shock resistance due to its low coefficient of thermal expansion (down to $7.5 \times 10^{-7} \text{K}^{-1}$ between 0 and 300°C), and as well as superior optical qualities. In contrast to pure fused silica, it can be easily fabricated in a variety of shapes.

As a modern material, borosilicate glass containing alumina can be drawn into continuous reinforcement fibers for windmill blade materials or discontinuous wool fibers for thermal and acoustic insulation. In recent years, borosilicate glasses have been extensively investigated with respect to their long-term chemical durability in relation to immobilization and disposal of radioactive wastes. In many countries, high-level radioactive waste has been incorporated into alkali borosilicate or phosphate glasses. Vitrification of a mixture of radioactive wastes and borosilicates is an attractive immobilization route owing to the high chemical durability of the vitrified products. It is desirable that the high chemical resistance of borosilicate glass enables the mixture to sustain a corrosive environment for many thousands of years. Typical compositions of borosilicate glasses for various applications can be found in Table 1 and will be described in subsequent sections.

Clearly, the main driving force for the fast development and enhancement of borosilicate glass products must be the requirement of developing a sustainable society and the desire to enhance the understanding of the correlations between the chemical composition, processing conditions, glass structure and properties. In turn, a better understanding of these relationships enable scientists and technologists to predict and tailor the properties of borosilicate glasses and develop new generations of glass products. In particular, the current understanding of borosilicate glass structure is substantially improved as compared to two decades ago, and this is thanks to advanced characterization techniques and computer simulations. This chapter reviews the progress both in revealing the structure of borosilicate glasses, and in predicting the glass properties by using the composition-structure-topology relation. Since there is a vast amount of publications and review articles concerning the structure and properties of borosilicate glasses, we will focus on describing the recent studies on these glass systems. After briefly reviewing some historic aspects of the structure studies, recent advances will be introduced concerning the impact of pressure and fictive temperature on structures of borosilicate glass, as well as the relation between medium-range order structural heterogeneity and thermodynamic properties. Atomistic computer simulation methods such as molecular dynamics that have played an important role in understanding the short and medium range structures and structure-property relationships of borosilicate glasses, as well as the recent developments of interatomic potentials for borosilicate glasses, are then introduced. After that, the recent progress in prediction of physical properties of borosilicate glasses, which have been made by both the rigidity theory and molecular dynamic simulations, will be presented. Finally, the important technological and industrial applications from lab and cook ware, fiber glass, optical and display, to nuclear waste disposal and biomedicine, as well as other potential applications, of borosilicate glasses are summarized.

Structure of Borosilicate Glasses

Characterizations

Short- and medium-range order structure

Like other glass and amorphous materials, borosilicate glasses lack long-range order and their structures are made up of networks consisting of $[\text{SiO}_4]$ and $[\text{BO}_4]$ tetrahedral units and $[\text{BO}_3]$ triangular units. This network features long-range disorder (beyond about 20 Å) and short- (~ 6 Å) and medium range (~ 6 –20 Å) order. The short-range order (SRO) in borosilicate glass means that the O-Si-O bond angle within $[\text{SiO}_4]$ units remains largely unchanged throughout the entire network, and this is the case for both $[\text{BO}_4]$ and $[\text{BO}_3]$ units. SRO also refers to the fact that the geometry of the structural units in the crystalline state can be inherited in

Table 1 Compositions of common borosilicate glasses for various applications

Glass/source	Oxide content, in wt%								Applications
	SiO ₂	B ₂ O ₃	Al ₂ O ₃	Na ₂ O	K ₂ O	CaO	MgO	Others

the glass state upon melt-quenching. Medium-range order (MRO) concerns the arrangement of a group of structural units in an ordered manner, e.g. some multi-member rings have similar structure throughout the network. Physical properties, phase transition behavior, and dynamic and thermodynamic properties of glass are governed by the structural characteristics over different length scales, especially by SRO and MRO domains, as well as different time scales. These properties are not only a function of chemical composition, temperature, and pressure, but also that of the entire thermal and pressure history. As for other classes of materials, the structural and topological characteristics of borosilicate glasses can be probed by means of advanced experimental and computational capabilities. The major challenge is to establish the quantitative connection between glass structure and properties, since often some rules based on established structural theories are not obeyed even for one- or two-component oxide glass systems.

The network structure of oxide glasses has been investigated using a variety of scattering and spectroscopic techniques. The first classical glass structure theory was the random network model proposed by Zachariasen (1932), in which the structural criteria for glass formation were established (Wright and Thorpe, 2013). After 53 years, Greaves (1985) proposed the concept of the modified random network, according to which there are two interconnected disordered regions: the polymerized one consisting of the glass formers and the depolymerized one composed of large concentrations of network modifiers. This concept has been confirmed by both experiments (Almeida *et al.*, 2014; Ojovan, 2016) and Molecular Dynamics modeling (Du and Cormack, 2004).

Recently, advances in instrumentation and new experimental methodologies have greatly enhanced understanding of glass structure at both short-range and intermediate-range length scales. One of the striking breakthroughs is the acquisition of direct experimental evidence for Zachariasen's random network theory (Huang *et al.*, 2012). Nuclear magnetic resonance (NMR) spectroscopy was first applied by Silver and Bray (1958) to determine the boron coordination numbers in borosilicate glasses. Today NMR has become a routine and powerful tool to characterize the SRO and MRO structure, as well as some long-range disorder structural features, of oxide glasses, owing to substantial progress and active development of NMR techniques. Such advances have led to a greatly enhanced understanding of glass structure and property for a wide range of inorganic glass systems. Particularly, for industrially relevant glass compositions containing B_2O_3 , SiO_2 and Al_2O_3 , their nuclear isotopes enable high-resolution NMR studies. The ^{11}B , ^{27}Al and ^{29}Si NMR techniques allow for probing local coordination environments of the network-forming cations. Accurate description of ^{11}B MAS NMR line shapes allows for separating different boron coordination environments, e.g., three-oxygen-coordinated boron (B^{III}) and four-oxygen-coordinated boron (B^{IV}), making it possible to determine the amount of boron involved in borosilicate glasses. It is the NMR method that first detected the most well-known important phenomenon – the *boron oxide anomaly*, in boron-containing glass (Yun and Bray, 1978). The advanced NMR techniques such as ^{11}B magic-angle-spinning (MAS) NMR and multiple quantum MAS NMR can even provide quantitative information on MRO structure, e.g., super-structural units like boroxol rings, and non-ring environments. Such structural information can be used to establish and optimize structural models of many commercial glass compositions. These models are the essential part of the topological constraint modeling procedure to predict physical properties of various glass systems including borosilicate glasses (Smedskjaer *et al.*, 2011).

Besides NMR, Raman spectroscopy is another powerful tool for exploring the SRO and MRO structures, as well as dynamics of boron-containing glasses. In Raman spectroscopy, a glass sample is illuminated with single wavelength (or single frequency) laser light, which can be absorbed, transmitted, reflected, or scattered by the sample. The detailed principle of Raman spectroscopy for characterizing glass structure can be found in literature (Almeida and Santos, 2015; and the references therein). Raman spectroscopy can often be used to identify the presence of terminal anions, like the non-bridging oxygen (NBO) ions in oxide glasses, which are associated with the presence of typical high-frequency peaks in the spectra. It is also crucial to combine theory with experimental Raman spectroscopy data. Glass phase separation, crystallization and other structural changes may also be conveniently followed by Raman spectroscopy.

Borosilicate glasses exhibit the interlinked borate and silicate networks. In Raman spectra of a borosilicate glass, the high frequency band of $>850\text{ cm}^{-1}$ is attributed to silicate networks consisting of tetrahedral silicon (Q^n), whereas intermediate frequency bands ($400\text{--}850\text{ cm}^{-1}$) are associated with MRO structural units, e.g., ordered superstructures such as reedmergnerite $[BSi_3O_8]^{-1}$ and danburite $[B_2Si_2O_8]^{2-}$ (Liu *et al.*, 2016). The bands from 300 to 500 cm^{-1} are characteristic of mixed stretching and bending modes of $Si\text{--}O\text{--}Si$ units, whereas bands in the range of $550\text{--}850\text{ cm}^{-1}$ are caused by ring breathing modes. The bands at 670 , 770 and 808 cm^{-1} are assigned to tetraborate groups, B^{IV} and B^{III} in diborate and boroxol rings, respectively. There are numerous articles dealing with the Raman spectroscopy analysis of borosilicate glasses (Almeida and Santos, 2015; Yadav and Singh, 2015).

Boron anomaly

The structural aspects of borate and borosilicate glass properties are fascinating owing to the boron anomaly. Boron anomaly refers to the phenomenon that a glass property varies non-monotonically with substitution of the network modifier for B_2O_3 in a borate glass system, i.e., a maximum or minimum occurs, depending on the type of property. The best known example is the minimum of the coefficient of thermal expansion (CTE) at a certain concentration of modifier (Uhlmann and Shaw, 1969). The anomaly has been ascribed to the competition between the formation of B^{IV} and the formation of non-bridging oxygens (NBOs). In detail, the initial incorporation of alkali or alkaline earth ions into a borate or borosilicate glass results in a decrease of CTE and an increase in glass transition temperature (T_g). However, after a certain concentration of network modifiers is reached, further addition of modifiers will gradually raise CTE and lower T_g . This behavior can be convincingly explained by the ^{11}B NMR data of a sodium borosilicate glass series, as shown in Fig. 1, where the fraction of the boron cations in BO_4 units (N_4) is plotted against the $[Na_2O]/[B_2O_3]$ ratio for the borosilicate system $Na_2O\text{--}B_2O_3\text{--}SiO_2$ with various $[SiO_2]/[B_2O_3]$ ratio (K values). N_4 increases with $[Na_2O]/[B_2O_3]$ ratio until the maximum value of N_4 is reached, and then it decreases. The increase of N_4 indicates an increased network connectivity, i.e., an increase in bridging oxygen (BO) fraction due to the gradual conversion of B^{III} into B^{IV} . This network tightening process lowers the extent of atomic vibrations upon heating, and thereby lowers CTE. After the maximum value of N_4 is reached, the fraction of BO continuously decreases and hence, the network is less connected. This leads to an increase in the extent of atomic vibration, thereby lowering CTE. The plots in Fig. 1 are separated into five groups, each corresponding to one K value ($[SiO_2]/[B_2O_3]$). As displayed in Fig. 1, the maximum values of N_4 and its corresponding $[Na_2O]/[B_2O_3]$ ratio increase slightly with K and can be determined by finding the intersection of the two lines for each group. In addition, the findings demonstrated in Fig. 1 has also been used to explain the boron anomaly related to other physical properties besides CTE, e.g., glass hardness

Fig. 1 Fraction (N_4) of the boron cations in BO_4 units versus $[Na_2O]/[B_2O_3]$ ratio for the borosilicate system $Na_2O-B_2O_3-SiO_2$ with various $[SiO_2]/[B_2O_3]$ ratios (K values) based on ^{11}B solid state NMR measurements. Reproduced from Yun, Y.H., Bray, P.J., 1978. Nuclear magnetic resonance studies of the glasses in the system $Na_2O-B_2O_3-SiO_2$. *Journal of Non-Crystalline Solids* 27, 363–380, with permission.

(Smedskjaer *et al.*, 2010). It should be mentioned that the experimental trend shown in **Fig. 1** has been beautifully reproduced by molecular dynamic simulation (see later section on Development of empirical potentials for MD simulations). This is an important step towards deeper insight into the atomic nature of the boron anomaly in borosilicate glasses.

Extensive studies have been conducted to enhance the understanding of the structural origin of the boron anomaly in both borate and borosilicate glasses. ^{11}B NMR was first used by Silver and Bray (1958) to determine boron speciation in pure boron oxide, alkali borate, and borosilicate glasses. Their seminal work built the basis for other scientists to establish the structural models for sodium borosilicate glasses (Yun and Bray, 1978). These structural models are a foundation of the currently derived topological models for predicting glass properties (Smedskjaer *et al.*, 2011). Furthermore, NMR was used to detect the impact of the thermal and mechanical history on boron speciation of borosilicate glasses.

Cooling rate and temperature effect

The fictive temperature (T_f) of a glass is the temperature at which the corresponding liquid structure and properties are frozen in upon cooling (Tool, 1946; Narayanaswamy, 1971; Moynihan *et al.*, 1976). It is a crucial parameter to describe its thermal history and a measure of the average level of its corresponding liquid on the potential energy landscape (Zheng *et al.*, 2019). The determination methods of T_f for any cooling rates are described by Yue *et al.* (2002). The increase of T_f with cooling rate q_c follows the relation (Yue *et al.*, 2004):

$$\log_{10} q_c = 11.35 - \log_{10} \eta(T_f) \quad (1)$$

where $\eta(T_f)$ is the viscosity at T_f of a glass quenched at q_c . The cooling rate (or T_f) has a pronounced impact on the structure and vibrational dynamics of the glass (Angell *et al.*, 2003). Specifically, increasing the cooling rate and T_f was found to enhance the excess density of vibrational states and the boson peak in glass, although its origin is still under debate (Chumakov *et al.*, 2014).

The direct evidence for an increase in NBO content with increasing T_f was achieved by performing NMR measurements on an E-glass composition (a typical borosilicate system) by Kiczinski *et al.* (2005). They found a correlation between T_f and the B^{IV} as shown in **Fig. 2(a)**, confirming the changes in boron coordination with cooling rate. Early on, Sen *et al.* (1998) also discovered the transformation of BO_3 units from boroxyl ring into non-ring configuration in a sodium borate system, and that of BO_4 units into asymmetric BO_3 units in a borosilicate system, with increasing temperature. No temperature-dependent speciation of the silicate units was observed in the borosilicate liquid.

It is seen in **Fig. 2(a)** that two clearly resolved peaks exist at 11 ppm and -1 ppm in the ^{11}B MAS NMR spectra, which were attributed to B^{III} and B^{IV} , respectively. As the quench rate increases, the proportion of B^{IV} decreases from 14% of the total boron in the slow-cooled sample ($T_f = 674^\circ C$), to 9% in the as-drawn fibers ($T_f = 912^\circ C$). When the fast-quenched sample ($q = 10^5 C/s$) was annealed at $43^\circ C$ above T_g and slowly cooled ($1.7 \times 10^{-2} C/s$) to well below T_g , the fraction of B^{IV} increased from 10% to 13%. Moreover, the ^{17}O -enriched E-glass samples had a similar dependence of the boron speciation on the fictive temperature to that of E-glass (**Fig. 2(b)**). As the cooling rate increases from $1.7 \times 10^{-2} C/s$ to $10^3 C/s$, and then to $10^5 C/s$, i.e., T_f increases from $674^\circ C$ to $807^\circ C$, and then to $872^\circ C$, the fraction of the B^{IV} species drops from 16% to 13%, and to 12%, respectively. In addition, raising T_f leads to an increase in the five-coordinated aluminum (Al^{VI}) content in E-glass and this is ascribed to the increase in F-Al bonds. The

Fig. 2 Impact of the cooling rate on the SRO structure for the E glass system with composition (mol%): $57.3\text{SiO}_2\text{--}6.0\text{B}_2\text{O}_3\text{--}8.7\text{Al}_2\text{O}_3\text{--}24.9\text{CaO--}0.9\text{MgO--}0.8\text{Na}_2\text{O--}0.8\text{F}_2$, and the ^{17}O -enriched sample with a major-element composition similar to that of the above E-glass. The meanings of the labels for the NMR curves are as follows. Slow: slow cooling (rate $q = 1.7 \times 10^{-2}^\circ\text{C/s}$, $T_f = 674^\circ\text{C}$); Water: water quenching ($q = 1 \times 10^3^\circ\text{C/s}$, $T_f = 807^\circ\text{C}$); Fast: fast quenching ($q = 1 \times 10^5^\circ\text{C/s}$, $T_f = 872^\circ\text{C}$); Fiber: fiber quenching ($q = 1 \times 10^6^\circ\text{C/s}$, $T_f = 912^\circ\text{C}$). The standard glass transition temperature (T_g) is 682°C . (a): ^{11}B MAS NMR spectra of E-glass samples. (b) ^{11}B MAS NMR spectra for the ^{17}O enriched sample. Data from Kiczinski, T.J., Du, L.S., Stebbins, J.F., 2005. The effect of fictive temperature on the structure of E-glass: A high resolution, multinuclear NMR study. *Journal of Non-Crystalline Solids* 351, 3571–3578, with permission.

high-temperature melt exhibits considerably higher $\text{B}^{\text{III}}/\text{B}^{\text{IV}}$, $\text{Al}^{\text{V}}/\text{Al}^{\text{IV}}$, and NBO/BO ratios compared to its corresponding glass with the standard T_g (Kiczinski *et al.*, 2005).

Wondraczek *et al.* (2007) systematically investigated the dependence of the SRO and MRO structure and thermodynamic properties on the mechanical history (pressure) and thermal history (cooling rate and T_f). They found that an increase in pressure and a decrease of T_f led to the decrease of the B^{III} species in sodium borosilicate glasses. The sensitivity of the boron speciation to cooling rate was also confirmed by Zheng *et al.* (2012). They found that rapidly cooled borate glasses have lower glass stability against crystallization than slowly cooled ones since the former contain more B^{III} species, leading to easy crystallization.

Pressure effect

The effect of pressure on glass structure has been extensively studied since it is a crucial aspect to be considered in designing and improving glass properties, as well as in understanding the nature of glass. Through these studies, substantial progress has been made in probing the evolution of both SRO and MRO structure in different glass systems during the *in situ* compression and/or in characterizing the structure after *ex situ* compression (Wolf and McMillan, 1995; Lee *et al.*, 2005; McMillan *et al.*, 2007; Yue *et al.*, 2007; Wu *et al.*, 2009; Striepe *et al.*, 2013). The pressure effect on borosilicate glass systems has also attracted attention of scientists as the boron speciation in these glasses is an effective, sensitive probe to reflect the pressure induced structural change (Svenson *et al.*, 2014; Wondraczek *et al.*, 2007).

Fig. 3 shows a typical example for detecting the boron coordination change induced by pressure (Svenson *et al.*, 2014). It exhibits the ^{11}B MAS NMR spectra of both the as-prepared and the 1 GPa compressed borosilicate glass with the composition of $60\text{SiO}_2\text{--}15\text{B}_2\text{O}_3\text{--}15\text{Na}_2\text{O--}10\text{CaO}$ (mol%). The spectra are characterized by a broad peak centered around +15 ppm, attributed to trigonal boron (B^{III}) sites, and a relatively narrow peak centered around 0 ppm, (which is caused by B^{IV}) sites. The fraction of

Fig. 3 ^{11}B MAS NMR spectra at 16.4 T of both the as-prepared and the 1 GPa compressed borosilicate glass samples with the composition (mol%) $60\text{SiO}_2\text{--}15\text{B}_2\text{O}_3\text{--}15\text{Na}_2\text{O}\text{--}10\text{CaO}$. The uncertainty of N_4 is ± 2.5 at%. Data with permission from Svenson, M.N., Bechgaard, T.K., Fuglsang, S.D., *et al.*, 2014. Composition-structure-property relations of compressed borosilicate glasses. *Physical Review Applied* 2, 024006.

tetrahedral to total boron numbers (N_4) is determined by conducting the spectral line shape simulation and subsequent peak area integration. It is seen in **Fig. 3** that N_4 increases from 70% to 77% upon isostatic compression at 1 GPa.

Another example is the combined picture concerning the impact of both pressure and fictive temperature on the thermodynamic and structure of a borosilicate glass as shown in **Fig. 4**. By measuring the dependence of pressure and cooling rate on the boron speciation of a borosilicate glass, Wondraczek *et al.* (2007) found that the changes in both the molar volume and the SRO structure were governed by the boron speciation in compression as well as in cooling experiments. They indicated the glasses with a given fraction of B^{IV} and a given molar volume could be achieved either by varying pressure or by changing cooling rate, e.g., by either 400 MPa and $4^\circ\text{C}/\text{min}$ or by 0.1 MPa and $10^{-4}^\circ\text{C}/\text{min}$. As mentioned before, the boron coordination in borosilicate glasses is NMR sensitive to their fictive temperature, as well as to pressure. **Fig. 4** illustrates that the ratio of $\text{B}^{\text{IV}}/\text{B}^{\text{III}}$ in the glass structure increases with decreasing cooling rate (i.e., fictive temperature) and increasing pressure.

Structural heterogeneity and thermodynamic behaviors

To understand the glass transition and thermodynamic properties of glass forming liquids, the structural and dynamic heterogeneities have become one of the key issues to be investigated (Yue, 2004; Matharoo *et al.*, 2006; Moesgaard *et al.*, 2010; Zhang *et al.*, 2013). The structural heterogeneity on intermediate length scale is also a crucial factor for determining glass properties, e.g., optical and photonic properties (Tan *et al.*, 2020), and thermodynamic behavior (Liu *et al.*, 2016; Ando *et al.*, 2018). The MRO structural heterogeneity has an intimate correlation with thermodynamic properties of glass. One of the evidences for this correlation was achieved by studying the impact of boron content on the configurational heat capacity as shown in **Fig. 5** (Liu *et al.*, 2016).

Fig. 5 shows the isobaric heat capacity curves obtained during DSC upscans at $10^\circ\text{C}/\text{min}$ for a borosilicate glass series with the molar compositions $(75-x)\text{SiO}_2 - x\text{B}_2\text{O}_3\text{--}15\text{Na}_2\text{O} - 10\text{CaO}$ with $x = 0, 6, 12, 24, 37.5, 51, 63$, and 75 (Smedskjaer *et al.*, 2011). The inset of the figure demonstrates how to determine standard glass transition temperature (T_g), glass heat capacity (C_{pg}), liquid heat capacity (C_{pl}), and the configurational heat capacity ($C_{p,\text{conf}}$). The difference (ΔC_p) between C_{pl} and C_{pg} is regarded as the approximate configurational heat capacity. The standard T_g is defined as the temperature at the crossing point between the extrapolated straight line of the glass C_p curve and the tangent at the inflection point of the sharp rise in the curve of C_p in the glass transition region. As shown in **Fig. 5**, the C_p curve rises and $C_{p,\text{conf}}$ increases with increasing B_2O_3 content. The T_g value first increases and then decreases with increasing B_2O_3 content.

Both $C_{p,\text{conf}}$ and T_g trends shown in **Fig. 5** are quantitatively represented in **Fig. 6(a)**. The relatively fast increase of $C_{p,\text{conf}}$ with B_2O_3 content in the silica-rich compositions can be attributed to the increase in both B-O-Si network units ($[\text{B}_2\text{Si}_2\text{O}_8]^{2-}$) and 6-membered borate rings with 1 or 2 B^{IV} . In the boron oxide-rich compositions, the $C_{p,\text{conf}}$ remains almost unchanged with B_2O_3 content. This could be ascribed to the balance between the decrease of the fraction of two types of metaborate groups and the increase of the fraction of other borate superstructural units (particularly 6-membered borate rings). T_g exhibits a non-linear trend with increasing B_2O_3 content, i.e., T_g first increases from 830 to 855 K as B_2O_3 initially substitutes SiO_2 , but then monotonically decreases to 777 K. Based on the temperature-constraint theory, this non-linear variation of T_g is mainly caused by the change of the temperature dependent constraints, and the short range order structural evolution of boron (Smedskjaer *et al.*, 2011).

The gradual substitution of B_2O_3 for SiO_2 may lead to the MRO structural change in borosilicate glasses, and this is verified by the Raman spectroscopy results (see inset of **Fig. 6(b)**). The inset of **Fig. 6(b)** shows the full range ($250\text{--}1650\text{ cm}^{-1}$) Raman spectra of the borosilicate glass series. The Raman spectra of borosilicate glasses can generally be divided into three main frequency regions: low-frequency ($300\text{--}550\text{ cm}^{-1}$), medium-frequency ($550\text{--}810\text{ cm}^{-1}$), and high-frequency ($900\text{--}1600\text{ cm}^{-1}$) regions. The assignment of the Raman bands to different vibrational modes has been described in detail by Liu *et al.* (2016).

Fig. 4 Fraction of B^{IV} atoms measured by ¹¹B MAS NMR spectroscopy for samples with the molar composition 16Na₂O–10B₂O₃–74SiO₂ as functions of both pressure and cooling rate. The samples were frozen-in at the cooling rate of 4°C/min under elevated pressures (triangle symbols), and frozen-in under ambient pressure but at different cooling rates (square symbols), respectively. On the pressure axis, positive values correspond to compression, and negative values result from extrapolation of the data and correspond to tension relative to the ambient pressure. Inset: NMR spectrum of the sample prepared under the condition of 500 MPa and 4°C/min. Data with permission from Wondraczek, L., Sen, S., Behrens, H., Youngman, R.E., 2007. Fig. 5 Isobaric heat capacity (C_p) curves determined by DSC at an upscan rate of 10°C/min subsequent to a downscan at the same rate, for the borosilicate glass series (75- x)SiO₂– x B₂O₃–15Na₂O–10CaO with $x = 0, 6, 12, 24, 37.5, 51, 63$, and 75 mol%, viz., with constant modifier content but varying [B₂O₃]/([SiO₂] + [B₂O₃]) ratio ($=x/75$). Inset: Illustration of determining glass transition temperature (T_g), glass heat capacity ($C_{p,g}$), liquid heat capacity ($C_{p,l}$), the difference between $C_{p,l}$ and $C_{p,g}$, ΔC_p , and the configurational heat capacity ($C_{p,conf}$) by taking the sample with composition with $x = 37.5$ mol%. Data with permission from Smedskjaer J.C., Mauro, M.M., Youngman, R.E., *et al.*, 2011. Topological principles of borosilicate glass chemistry. *Journal of Physical Chemistry B* 115, 12930–12946.

Fig. 6(b) demonstrates an approximately linear relation between $C_{p,conf}$ and the total area of all the Raman bands assigned to MRO structural units, i.e., the algebraic sum of the relative areas of each deconvoluted Raman band. This implies that the increase of $C_{p,conf}$ is linearly correlated with the increased diversity of the MRO structural units. The coordination conversions (i.e., SRO structural changes) have a small contribution to $C_{p,conf}$ in borosilicate glasses, i.e., the changes in the boron coordination account for 25% of the $C_{p,conf}$ (Angeli *et al.*, 2012). This suggests that the diversity of MRO structural units might have a larger contribution to $C_{p,conf}$ in these glasses.

According to the equipartition theorem of energy in statistical thermodynamics, the specific heat is directly linked to the atomic degree of freedom of motions. In borosilicate glasses, a variety of superstructural units containing different numbers of borate rings may involve more conformational states than the SRO structural units. As glass undergoes the glass transition region during heating, MRO structural units are thermally activated. This causes all of the superstructures to break down gradually, i.e., the rings separate from each other, leading to the formation of out-of ring or “loose” [BO_{4/2}][−] and [BO_{3/2}][−] units (Yano *et al.*, 2003). This structural evolution gives rise to the increase of the heat capacity. The change in the content of MRO units has no impact on the

Fig. 6 The connection of the dynamic (T_g) and thermodynamic ($C_{p,conf}$) properties to the degree of the medium-range order (MRO) heterogeneity, which is manifested by the total area of the MRO bands (see Inset), for the borosilicate glass series $(0.75-x)SiO_2-xB_2O_3-0.15Na_2O-0.10CaO$ with $x = 0, 0.06, 0.12, 0.24, 0.375, 0.51, 0.63$, and 0.75 mol. (a) The configurational heat capacity ($C_{p,conf}$) and the glass transition temperature (T_g) as a function of the $[B_2O_3]/([B_2O_3] + [SiO_2]) = x/0.75$. (b) $C_{p,conf}$ as a function of the total integrated area of the Raman band (61–850 cm^{-1}). Inset: The full range (250–1650 cm^{-1}) Raman spectra, which exhibit the vibrational bands associated with bridging oxygen, MRO units, tetrahedral SiO_4 units and the 3-oxygen coordinated boron (B^3), respectively. The total area of the MRO bands is the algebraic sum of the area of each deconvoluted IRO band. Reproduced with permission from Liu, H., Smedskjaer, M.M., Tao, H.Z., *et al.*, 2016. A medium range order structural connection to the configurational heat capacity of borate-silicate mixed glasses. *Physical Chemistry Chemical Physics* 18, 10887–10895.

SRO units (Yano *et al.*, 2003), and thus it is the increased diversity of MRO units that enhances $C_{p,conf}$ and hence the configurational entropy. This makes sense because the configurational entropy is a measure of the diversity of the structural arrangements. In the case of borosilicate glasses, an increase of B_2O_3 causes an extended variety of the superstructural units, and the size of these units is comparable to the length scale of MRO domains.

The topological heterogeneity in compressed sodium borosilicate glasses was explored using the Brillouin and in situ small angle X-ray scattering (SAXS) analyses by Reibstein *et al.* (2011). They extrapolated the SAXS intensity to very low angular regimes, and related it to compressibility. By performing both the Brillouin scattering experiments and the elastic property measurements, they determined the Landau-Placzek ratio, which reflected the amplitude of frozen-in density fluctuations. With increasing fictive pressure, the topological heterogeneity in the glass within both SRO and MRO ranges is significantly lowered. Through both the dynamic heating-cooling and the isothermal heating protocol, it was possible to detect the evolution of density fluctuations upon pressure recovery (Smedskjaer *et al.*, 2014b). The glass structure arrested by the pressure of 470 MPa was completely recovered to that corresponding to 0.1 MPa around the glass transition temperature. Based on the isothermal heating experiments, Reibstein *et al.* (2011) found that the medium- and long-range structure recovery govern macroscopic density relaxation.

Molecular Dynamics Simulations

Background

Molecular dynamics (MD) simulations have been an effective tool in the study of glass and amorphous materials. It is used to generate atomic level glass structures and compute the equilibrium and transport properties of a many-body system where the constituent atoms can be considered as particles which follow the laws of classical mechanics. MD simulations can in many ways complement experimental methods but it also has significant advantages in terms of providing detailed short and medium range structure characteristics in studying glass and amorphous materials. In MD simulations, samples of N number of particles are

taken, then Newton's law of motion for each of the particles is solved to determine its position and velocity in the next time step. Interaction over large number steps are performed until equilibrium is achieved. Based on formulations of statistical mechanics, various thermodynamic properties such as volume, pressure, internal energy, kinetic energy and enthalpy, and related properties such as heat capacity can be calculated (Daan and Smit, 2002). Therefore, in simple words, MD simulation is a technique to obtain various properties of a system by solving Newton's law of motion. Unlike crystalline materials, glass materials do not have long-range order but have short range order similar to related crystals. As a result, in many cases, it is difficult or even impossible to determine the structure of glass using common experimental characterization methods. MD simulations can overcome these barriers and provide valuable insights into the structure and properties of glass. In this section, MD simulations of borosilicate glasses will be summarized.

Development of empirical potentials for MD simulations

The major challenge faced in MD simulations lies in the choice of reliable and transferrable interatomic potentials that is capable to reproduce the glass structure under study (Du, 2015). About four decades ago, MD was first used to analyze silica glasses and since then it has been used to study oxide glasses as well as other amorphous systems. Growing interest in these realms resulted in the development of different types of interatomic potentials to simulate silicate and aluminosilicate systems. However, despite its growing significance in diverse engineering applications, MD simulations of boron-oxides have been a challenge in the glass community due to lack of reliable potentials. Boron (B^{3+}) can take three and four-fold coordination of oxygen, depending on the glass composition and thermal history. Boron anomaly, the non-linear composition dependence of the structure-property of these glasses, originated with the change in boron coordination with composition, which was confirmed by multiple ^{11}B NMR studies (Dell *et al.*, 1983; Wu and Stebbins, 2009). Recent developments on boron related parameters, however, have enabled MD simulations of multicomponent borosilicate glasses. Fig. 7(a) shows the fraction of four-fold coordinated boron (N_4) as a function of R (molar ratio of Na_2O to B_2O_3) and K (molar ratio of SiO_2 to B_2O_3) from MD simulations with potentials developed by Deng and Du (2019). The simulation result is compared with the Dell, Bray and Xiao (DBX) model (Dell *et al.*, 1983) that was based on ^{11}B solid state NMR and shows the quality of the potential to reproduce boron coordination in wide composition ranges.

MD simulations of borosilicate glasses previously used the Born-Mayer-Huggins (BMH) pair-wise potentials with integer charge values. It was able to generate the structure quite reasonably but mechanical properties were not in agreement with experiments (Kieu *et al.*, 2011). Also, to appropriately model such systems required potential sets with variable parameters to properly describe the changing boron environment with glass compositions. Considering this phenomenon, potential sets were developed by various groups of researchers (Takada *et al.*, 1995; Huang and Kieffer, 2003). Kieu *et al.* (2011) proposed a set of empirical potential with compositional dependent charges and A_{B-O} parameter for B-O bond. Later on, Deng and Du (2016) added aluminum parameter to this potential set. Deng and Du (2019) developed a set of empirical potentials with composition dependent A_{B-O} parameter (referred to as Du's potential). These potentials have long range Coulombic interactions and short-range interactions in the Buckingham format:

$$V(r_{ij}) = \frac{Z_i Z_j e^2}{4\pi\epsilon_0 r_{ij}} + A_{ij} \exp(-r_{ij}/\rho_{ij}) - C_{ij}/r_{ij}^6 \quad (2)$$

Fig. 7 (a) Fraction of four-coordinated boron, N_4 from the DBX model (solid lines) and simulated structures (dots) as a function of R at different K values; (b) N_4 obtained from Du, Kieu and Bauchy's potentials in Na_2O - B_2O_3 - SiO_2 glasses at $K = 2$. Reproduced from (a) Deng, L., Du, J.C., 2019. Development of boron oxide potentials for computer simulations of multicomponent oxide glasses. *Journal of the American Ceramic Society* 102, 2482–2505. Data with permission from (b) Tuheen, M.I., Deng, L., Du, J.C., 2020. A comparative study of the effectiveness of empirical potentials for molecular dynamics simulations of borosilicate glasses. *Journal of Non-Crystalline Solids* 551, 120413.

Despite similar potential form, the effectiveness of the potential differs significantly. This is shown in Fig. 7(b), where the boron N_4 as a function of R was plotted for three sets of potentials together with those from experiments and the DBX model. The results confirm that the Deng and Du potential (Deng and Du, 2019) has the best agreement with experiments in the whole composition range.

Composition dependent potential parameters are more effective in describing the boron anomaly as observed in the work of Tuheen *et al.* (2020). In this work, Du's (Deng and Du, 2019), Kieu's (Kieu *et al.*, 2011) and Bauchy's potential (Wang *et al.*, 2018) sets were compared. As discussed earlier, Du's potential set has composition dependent A_{B-O} and Kieu's potential has composition dependent A_{B-O} and ion charges. Bauchy's potential set focused on the transferability of the potentials and has all the parameters fixed. As seen in the figure, the potential sets, having composition dependent parameters (Deng and Du, 2019; Kieu *et al.*, 2011), are in better agreement with DBX model as well as experimental values.

Effect of cooling rate and system size on simulated glass structure and properties

Cooling rate used in MD simulations is many orders higher than in the laboratory. Some differences between experiments and simulation results were explained by the difference of cooling rates. MD simulations are performed in relatively small systems containing a few hundreds to tens of thousands of atoms. Therefore, energy exchange is much faster than practical experiment and thus use of high cooling rate is justifiable (Deng and Du, 2018). Again, this melt-quench does not involve heterogenous nucleation at an interface as long as a periodic boundary condition is used. Since the structures of boron-based glasses such as borosilicate and aluminoborosilicate depend on thermal history, glass researchers showed keen interest in the cooling rate effects on these glasses. For example: studies found a decrease in the fraction of four-coordinated boron (N_4) at higher cooling rate (Wu and Stebbins, 2010). In addition, glass annealing temperature can effectively act on the medium range structural units. Increased quenching rate was observed to create more disordered structures. Findings of MD simulations are further influenced by the system size. Deng and Du (2018) performed a systematic study of the effect of system size and cooling rate on the structures and properties of alkali borosilicate glasses. It was observed that both of these parameters can indeed alter the proportion of three- and four-coordinated boron which in turn affects the structure and properties of these glasses. A good agreement was obtained when the glass transition temperature T_g of the simulated glass was extrapolated to the experimental cooling rate. Furthermore, convergence tests are strongly recommended since different structure and property are found to converge at different system size and cooling rate.

Short and medium range structure information

Fig. 8(a) shows the initial configuration of a sodium borosilicate system before melting-quenching towards glass state in MD simulations. Fig. 8(b) displays the structure of the bulk glass generated from MD simulations (Ren *et al.*, 2017). It is clearly seen that the glass possesses network structure made up of SiO_4 tetrahedra, BO_3 triangles, BO_4 tetrahedra and AlO_4 tetrahedra. The glass composition $61.8SiO_2-16B_2O_3-3.8Al_2O_3-18.4Na_2O$ mol% is based on a model nuclear waste glass ISG (see later Section on "Nuclear Waste Disposal"). Glass surface structures are important to understand the surface reactivity and dissolution behaviors. Fig. 8(c) shows the surface structure of the glass from MD simulations. Importantly, it was found that the surface composition (and structural features) are slightly different from the bulk. In particular, there exists an enrichment of sodium on the top of the glass surface and there exist small membered rings that are usually not found in the bulk (Ren *et al.*, 2017).

A reasonable structure of boron-oxide glass generated by MD simulations is able to quantify other structural aspects such as the fraction of bridging and non-bridging oxygens (BO and NBO respectively), Q^n distribution (n is the number of bridging oxygens

Fig. 8 Bulk and surface structure of sodium aluminoborosilicate glass (composition $61.8SiO_2-16B_2O_3-3.8Al_2O_3-18.4Na_2O$ mol%) from MD simulations. Data with permission from Ren, M.G., Lu, X.N., Deng, L., Kuo, P.-H., Du, J.C., 2018. $\text{B}_2\text{O}_3/\text{SiO}_2$ substitution effect on structure and properties of $\text{Na}_2\text{O}-\text{CaO}-\text{SrO}-\text{P}_2\text{O}_5-\text{SiO}_2$ bioactive glasses from molecular dynamics simulations. *Physical Chemistry Chemical Physics* 20, 14090–14104.

in a tetrahedral unit, $\sim 0-4$). Short-range structural information such as bond distance and bond angle distribution of B-O pairs obtained from MD simulated boron containing glass is shown in Fig. 9(a) and (b) respectively. The deconvoluted partial distribution function of the B-O pair shows two peaks: the peak at ~ 1.4 Å represents three-coordinated boron whereas the peak at ~ 1.5 Å is due to the four-coordinated boron tetrahedra. Similarly, the bond angle distribution of O-B-O shows two peaks. These are at $\sim 109.5^\circ$ and 120° representing the tetrahedral and triangular boron species respectively. The addition of alkali oxide which is a glass modifier, bridging units such as Q^3 break down to generate species with more NBO such as Q^1 and Q^2 . As discussed earlier, in a ternary alkali borosilicate system, addition of sodium first converts three to four-coordinated boron, then the excess of sodium creates NBO around Si and with even further addition, sodium will create NBO for B species and four coordinated boron will revert back to three-coordinated B. Therefore, the number of NBOs associated with Si and B is also composition dependent and requires to be reproduced accordingly. As reported by Deng and Du (2019), potential sets with composition dependent parameters were able to quantify the NBOs which is in good agreement with the DBX model.

NMR spectra from MD simulations

It is possible to calculate NMR spectra based on glass structural models generated from MD simulations. These calculated spectra can be compared with the experimental ones. Fortino *et al.* (2019) assessed a ternary alkali borosilicate system with Du's and Bauchy's potentials (rigid ion model) and shell model based on potential proposed by Stevansson *et al.* (2018). In their work, ^{11}B , ^{29}Si , ^{23}Na NMR spectra were calculated using the Density Functional Theory (DFT) – Gauge Including Projected Augmented Wave (GIPAW) method (Fortino *et al.*, 2019) to compare the effectiveness of these potential sets. The shell based polarizable potential was found to be better describing the second coordination shell of Si. The rigid ion models resulted in good partitioning of three and four coordinated boron.

Other structural aspects: Boroxol rings and larger structural features

Borate and borosilicate glasses consist of different ring structures such as boroxol rings (three membered rings formed by connecting the bridging oxygens of $[\text{BO}_3]$), danburite-like rings (four membered rings connecting 2 Si and 2 B). Presence of smaller rings in the MD simulations can be well affected by the control of system size and cooling rate. Three membered rings formed by boron alone were found to be less common in the MD simulations of sodium borosilicate systems. Rather three membered rings formed by Si alone which is also of higher energy were observed in these structures. The number of smaller rings decreased with the increase of system size (Deng and Du, 2018). Therefore, larger system size results in a consistent number of small rings in simulations. Also, faster cooling rate gives rise to greater number of small rings which are energetically unfavorable. This is again another indication that thermal history of borosilicate glasses affects its structural features and properties.

Prediction of Physical Properties

Prediction by Rigidity Theory

To accelerate the discovery and design of new glass materials, it is critically important for scientists to be able to predict glass properties. In the past decade, substantial progress has been made in developing various approaches for predicting glass properties from glass composition and structure. One of the effective approaches is the rigidity theory (Phillips, 1979; Phillips and Thorpe,

1985; He and Thorpe, 1985). Initially, this theory was proposed based on a fully connected network at 0 K temperature. At $T > 0$, however, a constraint depends on the available thermal energy compared with the energy required to break the constraint. Gupta and Mauro (2009) extended the initial Phillips–Thorpe theory to account for the temperature effect, i.e., the so-called temperature-dependent constraint theory, and thereby they succeeded in predicting both the T_g and liquid fragility of borate systems. This theory treats the atomic structure of glass as a network of rigid constraints, and links the physical properties of glass to the composition, temperature, and pressure dependence of the number of these constraints. Using this theory, for the first time, Smedskjaer *et al.* (2010) accurately predicted the mechanical property of glass – hardness, by establishing a constraint counting model based on the structural data of a borate glass system. The modeled results reflected the boron anomaly effect. The principle of the T -dependent constraint theory is briefly described as follows.

Atoms in a structural network are constrained by their chemical bonds and bond angles. The strength of the constraints depends on the local topology and the charge and size of those atoms. Thus, detailed structural information, e.g., the atomic coordination numbers (CN) of the network formers is required to count the number of constraints per atom (n_c). Both the number of constraints determined by linear bond-stretching ($n_{c,linear} = CN/2$) and that determined by angular bond-bending ($n_{c,angular} = 2CN - 3$) should be summed to obtain the number of constraints (n) for each network-former. According to the temperature-dependent constraint model, a certain critical number of constraints (n_{crit}) must be present for the glass to possess mechanical resistance, i.e., for hardness to become non-zero in three dimensions. When $n < n_{crit}$, the mechanical response is liquid-like. When $n > n_{crit}$, there are enough constraints to make a rigid network a solid-like response. A value of $n = 3$ indicates that a network is rigid in three dimensions, such as the tetrahedral network of silica, which is fully polymerized. A network must be rigid in at least two dimensions to be mechanically resistant. This case corresponds to $n_{crit} = 2.5$ and represents a network that is exactly rigid in two dimensions of the three-dimensional space. The hardness (H_v) of a glass is thus proportional to the number of constraints in excess of $n_{crit} = 2.5$, i.e.,

$$H_v = H_v/dn(n - 2.5) \quad (3)$$

According to the temperature-dependent constraint model, each constraint is associated with an onset temperature, above which the constraints are broken and therefore should not be counted. The onset temperature is a measure of the strength of chemical bonds.

Here, an example for prediction of the hardness is presented in Fig. 10 for the borosilicate glass series with the compositions given in the figure caption (Smedskjaer *et al.*, 2011). Based on the NMR data, the number of the room temperature constraints (n) in this glass series is counted and then the proportionality constant dH_v/dn can be determined by fitting the measured H_v versus n relation to the linear function as shown in the inset of Fig. 7. By inserting n and dH_v/dn into Eq. (3), the hardness of each of the glass series can be calculated as exhibited in Fig. 10. It is seen that there is an excellent agreement between the measured and the calculated H_v values. It should be mentioned that both the two μ constraints per NBO-forming Ca atom and the two μ constraints per NBO-forming Na atom are taken into account when counting the n values. Otherwise, the calculated H_v values would deviate from the measured ones. However, the μ constraints associated with Ca should have a much lower onset temperature than those associated with Na.

Zheng *et al.* (2017) established the most accurate predictive model for silicate glass hardness by adopting the density of angular constraints, i.e., the number of constraints per volume. This model is confirmed to be more accurate than that based on the total number of constraints per atom as shown in Fig. 11. The total constraint density model works as well, since the composition

Fig. 10 Comparison between the measured Vickers hardness (H_v) values (Blue spheres) and those (red triangles and dash curve) predicted by the equation $H_v = H_v/dn(n - 2.5)$ for the borosilicate glass series with constant modifier content but varying $[SiO_2]/([SiO_2] + [B_2O_3])$ ratio, viz., $(0.75-x)SiO_2-xB_2O_3-0.15Na_2O-0.10CaO$ with $x = 0, 0.06, 0.12, 0.24, 0.375, 0.51, 0.63$, and 0.75 . dependence of the total constraints is dominated by the variation in the angular constraints. The total constraint density model has the additional advantage, i.e., it contains only one fitting parameter. Based on the findings of Zheng *et al.* (2017) and combining the approaches of Bauchy *et al.* (2015) and Lamberson (2016), it was concluded that the density of rigid total constraints or rigid angular constraints should be used as a metric for predicting hardness of oxide glasses including borosilicate glasses (Fig. 11).

In Fig. 11(a), the measured hardness values for the borosilicate glasses are compared with those predicted by two constraint models involving total constraint density, and total constraints per atom, respectively. It is seen that the best fit is improved when using the total constraint density rather than the total number of constraints per atom. Fig. 11(b) exhibits that the hardness values predicted using the angular constraint density model also excellently agrees with the experimental ones, while the hardness modeled using angular constraints per atom gives poor agreement. It should be mentioned that the hardness predicted using angular constraint density is slightly better than that using total constraint density.

In addition, to improve the prediction ability and accuracy of the T -dependent constraint models, considerable efforts have been made by glass scientists. The main progress is described as follows. First, the concept of constraint strength was introduced into the topological model, which is a measure of how strongly the modifiers are bound to the surrounding oxygens through columbic forces (Rodrigues and Wondraczek, 2014). Second, the topological model was extended by taking into account that the effective number of intact constraints per modifying cation linearly relates to the charge-to-distance ratio of the modifying cation to oxygen (Hermansen *et al.*, 2014b). Third, the temperature dependent constraint model was modified by considering the structural and topological role of the modifying ion sub-network constituted by alkali ions and their NBO coordination spheres, and thereby, the prediction accuracy of glass dynamic properties is improved (Hermansen *et al.*, 2014a).

Prediction From MD Simulations

Mechanical properties of glasses can be calculated based on the simulated glass structures (Hill, 1952). Bulk, shear and Young's moduli were calculated for borosilicate glass structures obtained from MD simulations and compared with experiments (Deng and Du, 2019; Tuheen *et al.*, 2020). The trend of these moduli followed the experimental values but there was quite an over estimation. When plotted against the sodium content i.e., molar ratio R , the curves of these moduli also represented the boron anomaly – an increasing value followed by a maximum and then decrease. For better prediction of mechanical properties of borosilicate glasses, the potential sets need further improvement. It can be observed from Fig. 12(a), mechanical properties are affected by system size of MD simulations. Moreover, from Fig. 12(b), it can be stated that the system size effect on mechanical properties is less dependent on change in N_4 value compared to the effect of cooling rate.

Fig. 12 System size effect on the (a) mechanical properties (b) N_4 and Young's modulus for the glass system $3\text{Na}_2\text{O}-\text{B}_2\text{O}_3-6\text{SiO}_2$. Data with permission from Deng, L., Du, J.C., 2018. Effects of system size and cooling rate on the structure and properties of sodium borosilicate glasses from molecular dynamics simulations. *Journal of Chemical Physics* 148, 024504.

When associated with an isobaric ensemble (NPT, constant number, pressure and temperature), it is possible to capture the final density of borosilicate glasses using MD simulations. Structure generated from MD simulations showed good agreement with the densities obtained from experiments at lower R value (~ 0.7) but deviation occurred at larger values of R (Deng and Du, 2019). Densities obtained for a ternary borosilicate system using Du's, Kieu's and Bauchy's potentials also showed similar results (Tuheen *et al.*, 2020).

Dynamic properties such as ionic diffusion behavior and vibrational density of states (VDOS) of borosilicate glasses can also be analyzed by means of MD simulations. Ren *et al.* (2018) derived the VDOS of a multicomponent boron-oxide system and compared the results with the first principle MD calculation (Pedesseau *et al.*, 2015). As shown in Fig. 13, three-coordinated boron gives rise to a peak around 680 cm^{-1} and the peak for four-coordinated species is located between 1100 and 1500 cm^{-1} .

Ionic diffusion properties in terms of diffusion co-efficient and diffusion energy barrier can be derived from mean square displacement calculations for the MD generated structure of borosilicate glasses. It was found that an increase in the substitution of B_2O_3 for SiO_2 causes a decrease in E_a for the ions in the high temperature range as shown in Fig. 14(a), while the sodium ion diffusion energy barrier at low temperature increases as can be observed in Fig. 14(b), which can be understood by an increase of network connectivity and more close network structures (Ren *et al.*, 2018). The significant decrease in E_a in the high temperature range is in accordance with the experimentally observed fact that adding sufficient amount of boron oxide decreases the melting point and viscosity of borosilicate glasses.

Applications

General Aspects

Borosilicate glass is an important glass type produced widely on the industrial scale and finds many technological applications from lab and kitchen ware, lighting and optics, display, to nuclear waste disposal and biomedicine. The earliest written record of borosilicate glass dates back to 1225 when a Song dynasty Chinese scholar Zhao Ru-Kuo wrote "borax is added so that the glass endures the most severe thermal extremes and will not crack" when describing glass production in Arabia and other places (Smith, 1997). Modern development of borosilicate glasses started from works by Michael Faraday in the UK and Otto Schott and Ernst Abbe in Germany in the 19th century. The research by Schott and Abbe on optical glasses systematically investigated the effects of boron oxide and other glass components on optical properties, which was essentially the beginning of glass science (Smith, 1997). They also found ways to produce borosilicate glasses and developed several thermal shock resistant borosilicate glass brands since 1917. In 1915, scientists at Corning Glass Works patented a low thermal expansion borosilicate glass marketed as Pyrex[®] (Jensen, 2006), which later became a household name due to its wide usage as cookware in kitchens and labware in laboratories.

Addition of boron oxide to silicate glass led to benefits both on glass properties and glass processing, as discovered by the early glass producers (Hubert and Faber, 2014). On the glass property side, it was found that boron oxide can lower the thermal expansion coefficient and increase thermal shock resistance, increase thermal conductivity and mechanical strength, enhance chemical durability and improve optical properties; while on the processing side, it was found that boron oxide can lower melting temperature, lower crystallization tendency, lower viscosity and increase working range of glass, as well as have more efficient dissolution of refractory raw materials. These advantages led to various technological applications of borosilicate glasses that will be discussed in this section. Fig. 15 shows examples of applications of borosilicate glasses from rail road lanterns, cook ware, pharmaceutical bottles, lab ware to display glasses.

Thermal Shock and Chemical Resistant Glass Vessels and Containers

The corrosion and thermal shock resistances of borosilicate glasses originated from their higher chemical inertness and lower thermal expansion coefficient as compared to conventional soda lime silicate glass. These properties make them ideal for glass labwares such as beakers, flasks and retorts that should be colorless and transparent, have high melting point, and resistant to water, acidic and caustic solutions, as well as be able to sustain thermal and mechanical stress. The discovery of borosilicate glass

Fig. 15 Applications of borosilicate glasses. Top left: railroad lantern, top right: kitchen ware, bottom left: pharmaceutical applications, bottom middle: lab ware, bottom right: display glass, center: fiber glass (images are from internet sources: Corning Glass Museum, Pyrex glass history, Corning display glass).

revolutionized the field of glass labware as it provides the ideal combination of the above required properties. Pyrex[®] from Corning and Duran[®] from Schott are among the most well known glass labware brands. Compositions of these and other common borosilicate glasses are listed in [Table 1](#). Both glasses have high silica (> 80 wt%), boron oxide (~ 13 wt%) and a small amount of alumina (~ 2 wt%) and (0–4 wt%) soda. Due to the high silica content, these glasses need to be melted at a higher temperature than the conventional soda lime silica glasses but they possess better thermal and mechanical properties, and higher glass transition and softening temperatures.

Corning's Pyrex is also a commercial success for cookware, especially for use in ovens. Cookware shares some similar requirements to that of labware such as high chemical durability, high thermal shock and mechanical stress resistance. Pyrex has become a synonym for high quality, highly resistant glass cook wares ([Hubert and Faber, 2014](#)). It is worth mentioning that there are current glass products with the Pyrex brand but which no longer have borosilicate composition. These kitchen ware products in the market use tempered soda lime silicate glasses, possibly due to cost considerations ([Smedskjaer et al., 2014a](#)).

Borosilicate glass is also the choice for ampoules and vials for medicine due to their chemical inertness and thermal shock resistance. They are called “neutral glass” due to their high chemical durability and, as a result, cations from the glass will not be leached to degrade the medicine. With the ongoing corona virus pandemic started in early 2020, borosilicate glass vials are in high demand as carriers of the vaccines. In addition to chemical inertness to protect the vaccine from contamination, some vaccines are required to be stored at low temperature (< − 70°C) but used at ambient temperature. Thermal shock resistance of borosilicate glasses is thus an additional advantage.

Glass Fibers and Wools for Insulation and Reinforcement

Borosilicate glass has been used in insulating (glass wool) and textile (long fiber) fiberglass and this is one of the largest technical applications of borates ([Smith, 1997](#)). The E-glass fiber, named after its ability for electrical insulation, as well as high chemical durability and mechanical properties, is among the most well known of the fiber glasses. The base composition of E-glass is calcium boroaluminosilicate with low alkali content (~ 1 wt%) (see [Table 1](#)). While highly resistant to moisture or water corrosion, E-glass fiber has low durability in acidic or caustic conditions. The C-glass fiber was developed to overcome this to be used in highly corrosive conditions. As compared to E-glass, all alkali oxides are removed from the C-glass fiber composition but B₂O₃ concentration is increased and MgO is substituted for some of the CaO. For some applications such as electronics, lower

dielectric constant is preferred. For this purpose, D-glass was developed. D-glass has higher silica (70–80 wt%) and boron oxide (15–20 wt%) concentrations but with lower alumina, alkali and alkali earth oxides. D-glass has poor chemical durability due to high boron oxide concentration. In addition to electrical insulation, E-glass and related fiber glasses also find applications in reinforced plastics or composites for various structural applications. It is worth noting that not all fiber glass is borosilicate based as some are silicate or aluminosilicate based.

Borosilicate glass has also been largely used in the production of glass wool for thermal insulation (Smith, 1997). Development of new borosilicate glass wool compositions and new processing techniques have led to a fiber glass revolution to replace traditional mineral wool as an insulation material. As compared to E-glass or other electrical insulation fiber glass, electrical conductivity is not a critical factor in glass wool for thermal insulation. Consequently, glass wool compositions (Table 1) have high alkali content (10–15 wt%) and typically contain 4–6 wt% boron oxide to lower the liquidus and working temperature to be suitable for the rotary fiberization process which is the preferred industrial process for production of glass wool.

Lighting, Optics and Display

The properties of borosilicate glasses such as low thermal expansion, resistance to high temperature and chemical corrosion, and some unique optical properties make them suitable for optical and lighting applications. In the early days, borosilicate glass was used for shatter resistant railroad lanterns. Modern lighting application also requires glass windows to withstand thermal shock due to different weather conditions. Borosilicate glass, due to its properties mentioned above, has been used in light fixtures such as sealed headlights, lamp covers, halogen bulbs and fluorescent tubes. Other borosilicate glasses, such as BK-7[®] of Schott (composition shown in Table 1) has low refractive index (~ 1.52) for visible light and low dispersion, together with high chemical durability and mechanical strength, are the ideal material for lenses, telescope mirrors, and other optical components.

Another important application of borosilicate glass is liquid crystal display (LCD) that is essentially omnipresent in our everyday life now from watches, smart phones, notepads, laptops, desktop computers to TVs and other large screen displays. Active matrix LCD requires the glass substrate to have thermal mechanical stability, precision geometry control, and perfectly smooth surfaces (Ellison and Cornejo, 2010). Alkali earth borosilicate glass is the basic composition of these display glasses (for example OA-10 glass from Asahi shown in Table 1). These glasses are essentially alkali free to avoid chemical and electronic interaction with the thin film transistor in Active matrix LCD. These glasses are commonly formed by what is known as the fusion technique in which the glass melt flows into a trough and overflows the walls to form a continuous thin ribbon of glass (Ellison and Cornejo, 2010). The formed glass ribbon has two contact free optical quality surfaces. The float technique, using a bath of molten tin, that is commonly used to form normal flat glasses is also used to fabricate LCD glasses but subsequent processing such as polishing of the tin side is required.

Nuclear Waste Disposal

Safe immobilization of nuclear waste is critical to the fuel cycle of nuclear energies. With the development of nuclear power as a clean energy source, more nuclear waste will be produced and need to be safely processed in addition to the defense nuclear wastes. Borosilicate glass is an internationally accepted waste form for nuclear waste disposal and the processing method is known as vitrification. Borosilicate glasses have several technical advantages as compared to other waste forms (Plodinec, 2000; Manaktala, 1992): (1) capability to incorporate a wide range of fission products and actinides; the common waste can have over 30 oxide components, (2) relatively low formation temperature ($< 1200^{\circ}\text{C}$) to be suitable for nuclear waste processing, (3) high waste loading, the ability to incorporate high proportion of waste (up to 40 wt%), (4) waste composition tolerance to accommodate variation of wastes from different sources, (5) resistance to radiation degradation, (6) ability to be produced remotely with simple and reliable process with minimum maintenance, and lastly (7) high resistance to aqueous corrosion and low susceptibility to leaching when in contact with ground water.

In the vitrification process, waste slurry and glass forming compounds known as frits are fed continuously to a melter where the mixture is electrically heated with ceramic electrodes (Manaktala, 1992). The resulting melt is then poured into stainless steel (or other metal) canisters and cooled down to below the glass transition temperature in several hours to days, depending on the canister dimension and cooling environment. The melting temperature of nuclear waste glasses is typical in the range of $1100\text{--}1200^{\circ}\text{C}$, much lower than for industrial glass manufacturing. The low melting temperature is mainly to avoid volatilities of radioactive fission products during the processing. Due to this and other reasons, such as large variations in compositions in waste glasses, the knowledge of industrial glass manufacturing sometimes cannot be directly applied to nuclear waste glass processing. Typical borosilicate glass waste compositions can be found in Table 1. The ternary sodium borosilicate AVM composition is the basic composition of most glass waste forms. SON68 (Table 1) is the French model nuclear waste glass with addition of alumina and calcia. Real waste glass compositions are usually much more complicated with up to 30 or more components.

The International Simple Glass (ISG) is a model nuclear waste glass that was designed to study the corrosion behaviors (Gin et al., 2013). Blocks of 500 g of ISG were prepared and distributed to research groups around the world to study the chemical durability, thermal, mechanical and other properties. As a model nuclear waste glass, the structure of ISG has also been studied by using characterization techniques such as solid state NMR, Raman spectroscopy, high energy X-ray and neutron diffraction (Kaspar et al., 2018; Lu et al., 2019a; Collin et al., 2018). Computer simulations such as molecular dynamics and Monte Carlo are also used

Fig. 16 Stages of corrosion of borosilicate nuclear waste glasses (top left). SEM image of the gel layer formation of a corroded borosilicate nuclear waste glass (top right). Water diffusion models in porous gel layer in borosilicate nuclear glasses (bottom left). Atomistic structure model of International Simple Glass (ISG) (bottom right) and zoomed in picture showing the cation oxygen polyhedra (middle right) from MD simulations. Data from Gin, S., Abdelouas, A., Criscenti, L.J., *et al.*, 2013. An international initiative on long-term behavior of high-level nuclear waste glass. *Materials Today* 16, 243–248. Structure of international simple glass and properties of passivating layer formed in circumneutral PH conditions. *npj Materials Degradation* 2, 4.

to study the structure and dissolution behaviors (Collin *et al.*, 2018; Lu *et al.*, 2019b; Deng and Du, 2019; Gin *et al.*, 2018; Kerisit and Du, 2019). The atomic structure of ISG glass generated from MD simulations is shown in Fig. 16 (bottom and middle right) and it can be seen that the network structure consists of SiO_4 tetrahedra, AlO_4 tetrahedra and ZrO_6 octahedra, while about 50% boron is four-fold coordinated and the other 50% three-fold coordinated (Collin *et al.*, 2018). Fig. 16 shows stages of nuclear waste glass corrosion, the atomic structure model of ISG from molecular dynamics simulations, and potential water diffusion pathways in the gel layer formed during glass corrosion.

One of the main reasons that borosilicate glass is chosen to immobilize nuclear waste is the high chemical durability in aqueous environment so the glass waste forms can last thousands to hundreds of thousands of years in the geological storage environment. Recent efforts have been devoted to understand the long term chemical durability of borosilicate nuclear waste glasses through intensive research in the US, France, UK, Belgium, Japan and other countries. It was discovered that the corrosion of borosilicate nuclear waste glasses mainly takes place in three stages (Gin *et al.*, 2013): (1) the initial fast dissolution due to ion-exchange of cations in the glass with protons or hydronium ions in the solution and hydrolysis of Si-O-B and Si-O-Si linkages, (2) the steady state corrosion after formation of a gel layer at the interface of the glass and the solution, and (3) a potential resumption of fast corrosion in certain conditions. The corrosion stages of nuclear waste glass are shown in Fig. 16 (top left). While the initial dissolution rate is fast, the residual dissolution rate can be very low and the steady state dissolution can last for thousands or hundreds of thousand years. An important finding from recent intensive studies is that the low residual rate of borosilicate glass dissolution is due to the formation of a silica rich porous gel layer that serves as a passivation layer and significantly slows down the reaction of the remaining glass (Frankel *et al.*, 2018). It was also found that the gel structure is rather dynamic and changes with time (Gin *et al.*, 2018). The reaction characteristics are controlled by the atomic- and micro-structures of the gel layer such as porosity and pore morphology. Solution chemistry such as pH, cation and anion concentration and external conditions such as temperature can also play an important role in nuclear waste glass corrosion. Under certain conditions, such as that due to precipitation of silica rich minerals, the residual dissolution rate can be disrupted and the glass corrosion resumes at a

high rate. Recent findings also suggest that the corrosion of glass can be affected by the corrosion products of metal containers, suggesting complex interactions in near field conditions (Guo *et al.*, 2020). Despite many of these findings, the exact nature of the residual and resumption corrosion are still topics of intensive scientific study.

Biomedical and Other Applications

Borosilicate glass also finds applications in biomedicine. Bioactive glass is a type of inorganic glass that can bond to soft and hard tissues through the formation of a hydroxyl apatite layer (the inorganic mineral component of bone) (Jones, 2015). The dissolution product of bioactive glass was also found to promote gene expression that facilitate tissue growth. As a result, bioactive glass is considered to be a type of third generation bioactive material. Bioactive glasses find applications in bone regeneration, dental and wound healing, and maxillofacial surgeries, commonly used in granular form or as coatings to metal implants, and as scaffolds for tissue engineering. The original bioactive glass as discovered by Larry Hench is silicate based: $\text{Na}_2\text{O}-\text{CaO}-\text{P}_2\text{O}_5-\text{SiO}_2$ (Hench *et al.*, 1971). The compositions of two common bioactive glasses 45S5 and S53P4 are shown in Table 1. These bioactive glasses experience incongruent dissolution while pure borate and phosphate based bioactive glasses, on the other hand, can dissolve congruently and generally dissolve much faster. As silicate based bioactive glass converts to hydroxyl apatite slowly, this leads to residual unconverted glass in vivo. Studies have found that addition of boron oxide can help to regulate the dissolution rate of the silicate based bioactive glasses while maintaining their in vitro and in vivo bioactivity (Lu *et al.*, 2018; Ren *et al.*, 2018; Lu *et al.*, 2017). As a result, partial or full substitution of silica by boron oxide in silicate based bioactive glasses (Table 1) has been studied to find the optimal level of substitution. Borosilicate glass is also used as coatings to load bearing metallic implants to serve as a bioactive interface between the metallic implants and the human body (Oliver *et al.*, 2019; Kuo *et al.*, 2019; Du and Xiang, 2016; Xiang and Du, 2011; Du and Xiang, 2012). Pure borate glasses have also been found to be bioactive and angiogenic. They have been fabricated into glass wool and used for wound dressing for healing of open wounds.

There are also other applications of borosilicate glasses. For example, they have been used in enamels, glazes and frits. Low thermal expansion of borosilicate glasses can have better thermal shock resistance, hence avoiding cracking or crazing of the glaze or enamel (Hubert and Faber, 2014). Another interesting application of borosilicate glass is porous glass based on the phase separation of sodium borosilicate glass in certain compositions. The formed glass is heat treated to form an alkali borate rich phase and a silica rich phase with the alkali borate phase being leached subsequently by using acid solutions, leaving the silica rich porous skeleton. This porous structure can be used for sorption, separation or catalysis support. Alternatively, the porous skeleton can be consolidated to form a high silica glass at a relatively low temperature. One example of such glass is the Vycor[®] glass by Corning, with 97 wt% SiO_2 and 3 wt% B_2O_3 in its final composition (Table 1).

In addition to the wide range of applications discussed above, it is believed that other potential applications will emerge as scientists and engineers discover new properties, behaviors and phenomena of borosilicate glasses that will lead to the next technological fronts as they have done in the past century.

Introduction

Chalcogenide glasses (ChGs) have received increasing global interest over the past decade due to their suitability for use in infrared (IR) systems (Zhang *et al.*, 2003; Eggleton *et al.*, 2011; Parvanov *et al.*, 2008; Sanghera and Aggarwal, 1999; Zhang *et al.*, 2004). With compositional tuning, their transparency can extend over the full IR spectral range (Zhang *et al.*, 2003; Eggleton *et al.*, 2011; Parvanov *et al.*, 2008; Sanghera and Aggarwal, 1999; Zhang *et al.*, 2004; Buff, 2016; Sissen, 2017; Yadav *et al.*, 2017; Goncalves *et al.*, 2018). Unlike oxide glasses (which have oxygen as a key anionic constituent), ChGs are part of a class of “non-oxide” glasses. This lack of oxygen (O) is important to their use and makes them transparent throughout the IR. Since most metal (M)-O species possess resonance absorption bands in the IR, the removal of oxygen, along with the removal of other potentially absorbing impurities (such as moisture (hydroxide, OH⁻, water, H₂O) and hydrides (M-H)) and any residual particulate from the melting process, is critical in ultimately defining the glass’ resulting transparency. Like halides (glasses based on group VII species), chalcogen (Ch) species (based on group VI elements) combine with other chalcogens or metalloids such as As, Sb, Ge and Ga, to form stable glasses with wide (compositionally-specific) glass forming regions. However, the bonds formed in these glasses are much weaker than M-O bonds and thus ChGs typically are softer, less chemically stable and have lower melting/softening temperatures as compared to oxide glasses. Additionally, due to the bonding present, ChGs can exhibit metastable properties including photosensitivity (radiation-induced structural modification) which varies both with glass composition and the material’s bandgap (defined by the bonds present) and type of exciting radiation (Kolobov and Tominaga, 2012). While these glass attributes may limit the material’s use in some instances, they can also be exploited to extend their use towards the realization of unique optical or physical property functionality (Carlie *et al.*, 2010). There are several excellent reviews on the basic attributes of ChGs for the interested reader that cover these topics (Hilton, 2010; Seddon *et al.*, 2006; Kolobov and Tanaka, 2001; Wang, 2014; Adam and Zhang, 2014; Richardson and Kang, 2020).

While ChGs and related alloys have been extensively studied since the early 1960s, there remains relatively few commercial products based on these glasses. Those that are available were largely developed in the 1960–1970 time frame, for xerographic and other bulk optical applications (Bixby and Ullrich (1956); Texas Instruments (1967)). Hence, these compositions are no longer protected by patents and hence are known by varying product names, manufactured by multiple vendors, such as Amorphous Materials, Umicore, Vitron, and SCHOTT AG. While ChGs were being developed internationally during this time, an excellent review of the history of the effort in the US starting at Texas Instruments and then at Amorphous Materials, including details of early glass development, melting methods, and glass properties, can be found in Hilton (2010). An additional source of data on numerous ChGs developed and/or measured in Russia can be found in Kokorina (1996). While the history of ChGs is rich, the small number (currently 6) of commercially produced compositions is largely due to limited demand of these glasses which until recently, have only been employed in a few *bulk* optical applications (such as in lenses for IR imaging systems). The most common of these has been in IR vision systems (so-called “forward looking IR” or FLIR systems) that allow vision in dark or foggy systems while driving. More recently, use of these glasses in commercial systems such as iPhones has broadened their use and familiarized the public with technology that was previously used solely by the military. Hence, efforts to scale the manufacturability of the glasses to include their forming into suitable, low cost lens elements and systems has led to wide scale academic and industrial work in techniques such as precision glass molding (PGM).

With expanded interest in sensing, security and imaging since 2010, the market for low cost alternatives to expensive crystalline optics such as Ge and Si, has invigorated ChG research efforts worldwide. This common “chicken and egg” conundrum exists for these IR materials, in that, without sufficient chemistry-structure-property data on candidate glasses that can be scaled to commercially-relevant sizes, optical designers cannot put these media into optical design codes that make the scale-up and commercialization of the new compositions economically viable. This blockage, however, has started to ease in recent years, as new data has been published by many groups who have worked to extend lab-scale melts to commercially viable sizes (Gibson *et al.*, 2019). Here, important characteristics required for data sheets include the glass’ transition temperature (T_g), refractive index (n) and its variation with wavelength, ($dn/d\lambda$) or temperature (dn/dT) along with the glass’ viscosity (η) and coefficient of thermal expansion, (CTE). All of these properties are composition specific, challenging to produce with superb repeatability unless made in controlled large scale melting production, and expensive to measure. Additionally, applications may or may not require ultra-high purity for low loss applications at specific wavelengths, and this requirement entails additional processing and cost consideration. Hence, unlike oxide glasses where most of these hurdles have been overcome in the ~100 years that companies have been making those glasses, these challenges still impede production and adoption of new ChG compositions into optical systems. Hence, as optical design teams work to integrate promising candidate materials into new, higher volume optical designs, this will reinforce the need of new glasses and encourage market attractiveness to glass producers.

This chapter discusses glasses and composites based on glasses, multi-phase (glass + crystalline) media where controlled crystallization has been employed to extend their properties towards use as glass ceramics (GCs). For brevity, we confine our discussion to the use of ChGs or GCs to optical applications, with reference to very recent advances in applications where these materials are passive (i.e., examples where the ChG does not contain a rare-earth or transition metal dopant for luminescence purposes). Highlighted are examples of how ChGs can be tuned through composition (glass' chemical constituents), morphology (the glass' homogeneous or phase separated nature), and microstructural modification associated with the controlled nucleation and growth of nanocrystal phases within the parent glass matrix to realize novel functionality (Buff, 2016; Sisken, 2017; Yadav *et al.*, 2017; Richardson, 2018; Li *et al.*, 2014; Yang *et al.*, 2007; Wang *et al.*, 2009; Zhao *et al.*, 2005; Xia *et al.*, 2006; Sisken *et al.*, 2019; Kang *et al.*, 2018a,b; Richardson *et al.*, 2016; Yadav *et al.*, 2019). Briefly discussed is a short summary on the state of the art in exploiting these compositionally defined attributes to enable low cost lenses created via PGM. This chapter discusses key material attributes to ChGs' and ChG-based GCs' for use in the IR. Specifically highlighted are uses in applications for the mid-wave IR (MWIR) spectral region in applications such as low cost lenses via PGM, fibers (communication) and introduces recent progress on new opportunities such as gradient index optics (imaging), low-loss waveguides (signaling), and optical nonlinearity (sensing and lighting).

ChGs: For Bulk Media and Fibers

Processing Characteristics of ChGs

ChGs are amorphous, non-crystalline solids formed largely by the fusion process (often called the melt-quench process) whereby elemental starting materials from group VI and other metalloids are combined and melted in a sealed quartz ampoule prior to homogenization, quenching and annealing. Unlike oxide glasses which can be melted in open crucibles, the high vapor pressures of chalcogen species such as sulfur or selenium, require melting in a sealed container. While melting in a fused silica ampoule may introduce minor oxide impurities to the melt (and for some applications is unacceptable), this trace level of contamination comes with the added benefit of poor wetting. As shown in Fig. 1, this enables melted ChG "rods" to be seamlessly released from their crucible with minimal sticking. Sulfide glasses and glasses containing alkali tend to react more with the crucible and in these melts, ampoules are often coated with carbon to minimize interaction and adhesion (Martin and Boyer, 1990). Such optimization has been shown especially useful in the examination of ChGs for battery applications where doping with Na or Li requires shielding from interaction with the glass crucible ampoule. Such processing considerations are required in the melting of these glasses as their properties can be adversely influenced by such melting environment variables that impact glass properties and crystallization stability.

Crystallization Stability and Compositional Trends

A glass' network structure is defined by its thermal history, i.e., the path that the melt takes from the liquidus melt to form a solid at room temperature. How that glass structure organizes is influenced by the cooling rate used and thus bulk glasses require annealing as their large aspect ratios (interior versus exterior skin) can see vastly different cooling rates that can induce stress and stress birefringence. This volume effect is much less pronounced in the thin diameters of optical fibers where cooling rates are very high. Despite the low thermal conductivities of glass, most fibers do not possess excessive density variation due to forming temperature gradients that degrades their refractive index homogeneity if the preform is compositionally homogeneous. Such thermal history and the distance the glass network is from its "equilibrium state" (for purposes of this discussion, not the state of the equivalent crystal, but that of a well-annealed bulk glass) will impact the resulting glass' properties as well if cooling was sufficient to avoid the nucleation and growth associated with crystallization. Crystallization in all glasses, but especially in fibers, leads to both absorption and scatter loss and thus, needs to be avoided. Various reviews on crystallization behavior in ChGs have been made (Hari *et al.*, 1998), and a subset of topics important to fibers are discussed in more detail here.

Crystallization in glass relies on nucleation and subsequent growth of crystals. Without the formation of stable nuclei, subsequent crystallization cannot occur. Crystallization in glass, in most cases, is undesirable and this is especially true in bulk optical

Fig. 1 A batched sulfide (yellow) and selenide (black) ChG prior to melting in a sealed ampoule (a); a 250 g rod of selenide glass after melting (b); shown as a reference for size is a US quarter.

glass and glass fibers where the presence of crystallites can result in scattering loss due to refractive index mismatch. To understand the key conditions of crystallization which must be avoided to ensure low optical loss fibers, one must be familiar with the temperature dependence of both nucleation process in ChGs and the subsequent growth of crystals should stable nuclei form. Stability against crystallization is often inferred by the difference between T_x , the onset of measured crystallization in a glass as indicated by exothermic heat release during thermal analysis measurement (such as differential scanning calorimetry, DSC) and the material's glass transition temperature, T_g . When this temperature difference, ΔT , exceeds $\sim 100^\circ\text{C}$, it is generally considered that a glass can successfully be formed into fibers, avoiding crystallization. Since non-oxide glasses typically have T_g 's much lower than oxide glasses, an estimated ΔT provides an initial insight on how composition, dopant type, and concentration can impact crystallization stability and the probability of being able to fabricate low loss optical fiber. However, a variety of historic references to measurement of critical cooling rates (CCR) of chalcogenide melts as a function of composition (Kokorina, 1996; Mikhailov and Tver'yanovick, 1986) and the role of variation in annealing protocols on refractive index provides insight into the intricacies of such measurements.

It is sometimes difficult to compare compositional dependency of ChG stability across authors, as measurements of ΔT are dependent on measurement heating rate used, which may not always be reported. However, it is useful to see the role compositional variation (rather than configurational variation) plays in glass stability. To illustrate the trend, a common set of glass systems is compared, as shown in Fig. 2 (Adam and Zhang, 2014). Here, two families of $\text{Ge}_{28}(\text{As/Sb})_{12}(\text{S}_x/\text{Se}_{60-x})$ are compared for their stability, ΔT illustrating that stability is largely dominated by chemical rather than configurational effects. In these glasses, only isostructural substitutions have been made to the glass network (as both As and Sb have a CN = 3) and S and Se are both two-coordinated. Hence, the network role of the chemical constituents in these two glass families (comparing As and Sb) are similar, but the magnitude of stability is defined by the type of the lower coordinated species (S or Se) and its quantity. Fibers based on Ge-As-Se-Te glasses have shown some of the lowest losses in ChG fibers investigated and it largely can be attributed to the glass' crystallization stability. As discussed by Shiryaev *et al.* (2004), $\text{Ge}_x\text{As}_{40-x}\text{Se}_{40}\text{Te}_{20}$, where $x = 0-40$, exhibit T_g that ranges from 140 to 320°C depending on Ge content and heating rate. Glasses with less than 35 mol% Ge showed no exothermic features associated with crystallization, indicating impressive high glass stability. Glasses within the ranges of Ge: 6–24 at% and Te: 42–48 at% were shown to have T_g above 200°C with no sign of crystallization during annealing for 20 h at temperatures exceeding T_g by $50-100^\circ\text{C}$ (Tikhomirov *et al.*, 2004).

Nucleation and growth theory can be applied to ChG materials for a variety of fundamental and applied reasons. A summary of these theories and methods to calculate nucleation and growth rates from experimental data (as specifically applied to Tellurite glasses) can be found in Massera (2009). The same protocols have been employed to ChGs as discussed below, to realize optical glass ceramics, where the secondary crystalline phase has a refractive index match to the parent glass to minimize loss. Examples of controlled crystallization in ChGs have been shown to be effective in realizing bulk glass ceramics (to either enhance thermal or mechanical stability (Sharma *et al.*, 2020)), create gradients in refractive index (GRIN) (Richardson, 2018; Siskin, 2017; Kang *et al.*, 2018a,b; Kang *et al.*, 2020a,b) or in commercial products resulting in optical memories based on GeSbTe phase change media (PCM) (Adam and Zhang, 2014; Zhang *et al.*, 2019). Recently, efforts to tailor crystalline phase formation in reversible, low optical loss PCMs for conformal coatings and the formation of permanent optical function realized through optical nanocomposites in bulk and films of ChG have shown that both compositional tuning and the associated understanding of crystal nucleation and growth kinetics can be exploited for new optical applications (Kolobov and Tominaga, 2012; Kolobov and Tanaka, 2001; Richardson and Kang, 2020; Bixby and Ullrich, 1956; Texas Instruments, 1967; Gibson *et al.*, 2019; Richardson, 2018; Kang *et al.*, 2019; Mingareev *et al.*, 2019). Here, tailoring of physical properties through the controlled formation and growth of specific

Fig. 3 Temperature dependence of nucleation and growth rates in undoped (data sets 3 & 4) and doped (data sets 1 & 2) $\text{Pr:}(\text{Ga}_2\text{S}_3)_{0.7}(\text{La}_2\text{S}_3)_{0.3}$ glass. The shaded region illustrates the increase (note logarithmic scale) in both nucleation (W) and growth (V) rates with Praseodymium doping level in the glass matrix.

secondary crystalline phases with defined volume fractions can lead to optical function not realized in static glass or crystalline media.

In fibers, crystalline phase formation is largely undesirable and thus, should be avoided. Knowledge of a glass' nucleation and growth rates provides quantitative insight into this process. The formation of rate versus temperature plots for both nucleation and growth (referred to by either I or W to denote nucleation rates and V or U to define growth rates) provides insight not only on the temperatures where crystal nuclei can form, but also at what temperature they grow and at what rate. Clearly, for most optical fiber glass compositions, one desires to operate in temperature regimes where a glass' nucleation rate is very low, and the growth rate for any small concentration of nuclei present approaches zero. This is the target for creating crystallite-free fibers. However, should one want to "selectively" create (or sustain) a nanocrystalline phase within the candidate glass system, knowledge of a glass' I - U curve and its use in defining optimal draw conditions will indicate what extent of crystallite formation and/or growth might occur. The selective use of this strategy for engineering controlled crystallization in tellurite cladding glasses showed that nanocrystal phase formation, known to enhance mechanical properties, was an efficient means to strengthen the outer layer of fibers formed in these typically crystallization-prone glasses (Massera *et al.*, 2010a,b).

Crystallization stability can be influenced not only by network constituents, but also by dopants. The variation in nucleation and growth behavior with doping is especially important when considering compositional selection of rare-earth doped ChGs such as in the development of active media. Since fibers of active, rare earth doped ChGs are one of the leading areas of interest for their use (Richardson and Kang, 2020), we highlight here this effect as example. The impact on both the nucleation and growth behavior of the glass with addition of the rare earth dopant praseodymium is noted in the study by Dianov *et al.* (1997). While illustrated in one ChG composition GaLaS, the impact on both the nucleation and linear growth rate with Pr doping is clear. Fig. 3 shows the variation (data set 1 and 2) in nucleation (W) and growth (V) for $\text{Pr:}(\text{Ga}_2\text{S}_3)_{0.7}(\text{La}_2\text{S}_3)_{0.3}$ glass as a function of temperature (K) as compared to the undoped material (data set 3 and 4). At the common temperature of 870K (highlighted with gray shading), comparing the rates for nucleation and growth, one observes that as compared to the undoped glass, the doped glass exhibits an almost 10-fold increase in nucleation rate, along with a concurrent increase in growth rate (approximated to $\sim 200 \times$). These data suggest that the dopant's presence in the glass network increases the likelihood that stable nuclei will form and once formed, will grow at a faster rate. This infers that measurement of nucleation and growth rates on actual compositions is needed to inform the expected crystallization stability of the material upon fiberization.

Viscosity (η) and Temperature (T) Dependence

A glass' viscosity (η , in units of Pa s) and temperature (T) dependence is a material-specific attribute, defined by the bonding in the glass matrix and to first order, the glass' average bond strength. For ChGs, this attribute is especially important in applications such as precision glass molding (PGM) and in the drawing of optical fibers. Defining the suitable fiber draw conditions (draw temperature and draw rate) is a fairly straight forward process when a glass' viscosity- temperature (η - T) behavior is known. Since core and cladding glasses should have similar T_g and CTE behavior to ensure compatibility during drawing, it is assumed that the η - T response of these two glasses, while differing slightly in index, will be close in both their thermal position (lateral shift) and curve steepness. These attributes of a η - T curve and its shape are important as they determine whether the glass has a short (steep) slope or long (less steep) range of processing temperatures. This short/long nomenclature is often used to highlight the ease (long) or difficulty (short) by which a glass can be fiberized as these terms define the temperature required for both flow and sometimes avoidance of crystallization. A similar η - T behavior between core and clad glass allows fiber drawing with minimal interface defects

Fig. 4 (a) An overview of the viscosity regions for a ChG, showing the ranges for measurements [left] and hot-forming applications [right], (b) a comparison of the viscosity and volatilization curves for $\text{Ge}_{10}\text{As}_{40}\text{Se}_{50}$ glass showing evidence of out-gassing in the molding region. (bubbles, trapped gas, or micro-delamination). Such defects would compromise (increase) the measured loss of the fiber. The literature contains multiple examples of such data for some ChG compositions, but as it is a time-consuming and instrumentation-specific measurement to make. Hence, such data are often not reported for more exotic or exploratory glasses as considerable measurement and specific sample fabrication are required and exploratory melts are frequently small in volume and not homogeneous.

Measurements of thermal properties including glass viscosity behavior as a function of composition is well studied. A detailed discussion of experimental methods and typical thermal behavior in ChGs is reviewed in Adam and Zhang (2014). Fig. 4(a) highlights the key thermal signature regimes for viscosity illustrating the measurement methods (left side of Fig. 4(a)) and the typical glass processing windows for typical glass manufacturing protocols (right side of Fig. 4(a)). Of relevance to the topic of ChGs for fibers are the temperature range for extrusion (10^2 – 10^9 Pa s) such as that for forming extruded rods or cane and that for fiber drawing (10^4 – 10^5 Pa s). These ranges will vary with composition and may vary with individual fiber drawing apparatus, but are generally accepted as a guide to predicting variation in formation behavior with composition. Fig. 4(b) overlays a η - T curve for a GeAsSe glass with a thermogravimetric spectrum that defines the weight loss of that glass with temperature. Shown in the figure is evidence that the onset of volatilization of glass constituents occurs near the low temperature range of precision glass molding. As compared to the data shown in Fig. 4(a), this temperature range is below the temperature range where fiberization for this glass takes place (at $\eta \sim 10^4$ – 10^5 Pa s), thus suggesting that compositional variation during drawing could occur without strict temperature control. Such compositional variation (volatilization) could lead to accompanying refractive index variations if special care is not taken to control temperature excursions for ChGs.

Fig. 5 illustrates how a characteristic viscosity-temperature curve varies with composition for a simple binary As–Se glass (Musgraves *et al.*, 2011). This plot is illustrative of the correlation between glass fluidity and network structure. Several key points are important to highlight when evaluating viscosity in ChG glasses by multiple experimental (such as by beam bending viscosity (BBV) – shown as the lower temperature data points and parallel plate viscometry (PPV) – shown as the upper temperature data points). Not shown are points defined by the fiber elongation method which requires fibers to be formed and measured using a specialized set up to yield data through the region ($\sim 10^{7.6}$ Pa s). Firstly, while there are varying discussions on the best means to “fit” experimental data (Mauro *et al.*, 2016), most literature data employ the Vogel-Fulcher-Tammann (VFT) method. The steepness of the viscosity curve is indicative of the working range available to draw, but the lateral position (in temperature) provides a gauge of the variation in energy needed to sever the structural units present to initiate flow. Glasses to the left in the series have much lower three-coordinated As present and thus a higher Se content which in this binary system, forms rings and chains of Se. Se–Se bonds have a lower bond energy than As–Se bonds and thus, these higher Se content glasses see an onset of flow at lower temperatures. The similarity in the shape of the series of curves is testament to the structural role of the primary bonds, found in the $\text{AsSe}_{3/2}$ pyramidal units that make up the “building blocks” in this glass and the Se_n chains that interconnect the pyramids. $\text{As}_{40}\text{Se}_{60}$, the stoichiometric glass contains only interconnected pyramidal units and no homopolar Se–Se bonds.

These data are especially important when considering the formation of low cost optics such as lenses prepared by a precision glass molding (PGM) technique. Often simply referred to as “molding”, the primary objective is that the glass be sufficiently stable to crystallization (have a high ΔT) to not devitrify upon the reheating cycle that accompanies the molding process. Secondly, it is desirable that a suitably short (and thus cost-effective) molding cycle be created whereby glass can be loaded into a molding machine, rapidly heated to a suitable molding temperature (as defined by its viscosity such as shown in Figs. 4(a) and 5), be fluid enough at that temperature to form a desired shape under an applied load, then be cooled such that the load can be

Fig. 5 Viscosity curves for the $\text{As}_x\text{Se}_{100-x}$ glass family from $x = 10$ (left-most) to $x = 40$ (right-most) obtained through beam bending and parallel plate viscometry. Reproduced with permission from Musgraves, J.D., Wachtel, P., Novak, S., Wilkinson, J., Richardson, K., 2011. Composition dependence of the viscosity and other physical properties in the arsenic selenide glass system. *J. Appl. Phys.* 110, 063503. Copyright 2011 AIP.

released and the cooled lens can be ejected from the machine. While simple in principal, the process is complex as there are various levels of property changes imparted to the glass by this “new” thermal history. Not only does the glass network structure change, but so too does its density, refractive index and, depending on composition, other aspects such as relaxation phenomena. Here, a glass’ network undergoes time dependent changes with temperature. Since ChGs have T_g which in some cases are as low as $\sim 100\text{--}200^\circ\text{C}$ above room temperature, there exists enough thermal driving force at room temperature, to cause time dependent variations in properties with time at room temperature. This is important in systems that must perform over a range of temperatures where the change in an optical system’s focus, needs to remain stable. This effect has been studied in a variety of publications, which have been summarized for a variety of ChGs in Koontz (2014). Hence, while interesting and more widely applied for a wide variety of ChGs being employed in low cost IR imaging systems, molded IR optics still require optimization for specific commercial applications where their thermal and physical properties play a guiding role.

Novel Optical Function and Gradient Properties

The above discussions highlight properties of ChGs which like other oxide and halide glasses, are important for their use as glasses or glass ceramics and how these properties often impact their manufacturability. Discussed in subsequent sections is how one can exploit some of the common misconceptions of ChGs towards generating unique function. Often, ChGs are seen as “limited” in their use due to their bonding and the impact of this on function. As discussed by Carlie *et al.* (2010), this “perceived” set of limitations (low T_g , weak (er) bonds, low chemical durability, poor thermal stability) can be used towards deliberate modification of any physical properties. Below, we focus on such knowledge to optimized aspects of optical function in ChGs.

GRIN via Spatially Controlled Nucleation and Growth

To control and manipulate light propagation in bulk imaging systems, multiple optical components are selected and combined to realize the desired optical function, across a defined spectral window. Here, individual IR optical components comprised of varying optical materials (glasses, crystals, and semiconductors) are often fabricated into complex, non-planar geometries exploiting their unique optical properties (Zhang *et al.*, 2003; Cha *et al.*, 2012; Hisakuni and Tanaka, 1995; Ramachandran *et al.*, 1997; Beadie *et al.*, 1998; Saitoh and Tanaka, 2003; Sanchez *et al.*, 2011; Kumaresan *et al.*, 2013). Legacy optical design and fabrication strategies often require costly multi-step manufacturing processes which limit system design flexibility, and this can lead to an increase in the size, weight, and power consumption (SWaP) potentially impacting both the performance and/or cost of the resulting imaging system (Zhang *et al.*, 2003; Cha *et al.*, 2012; Hisakuni and Tanaka, 1995; Ramachandran *et al.*, 1997; Beadie *et al.*, 1998; Saitoh and Tanaka, 2003; Sanchez *et al.*, 2011; Kumaresan *et al.*, 2013; Booth, 2014). These issues can be significant in bulk IR systems where high density crystalline materials are widely used, as these optical materials possess monochromatic/chromatic aberrations and/or limitations in performance at elevated temperatures (Moore, 1980; Li, 1980). Next-generation imaging systems will require materials with enhanced multi-spectral or broadband optical functionality, thus further challenging the aim to reduce the number of components in an optical system and resulting platform footprint. Reducing SWaP in optical

systems through the creation and use of IR nanocomposite materials possessing GRIN profiles provides a viable solution to this challenge (Moore, 1980). Here the optical composite, in the form of a bulk component or planar waveguide, can yield a uniquely tailorable solution exploiting tunable optical function created by combining the desirable attributes of effective media. A key strategy to create GRIN profiles within a single medium involves spatial control of a high refractive index phase in a medium. Conversion of a base glass to a glass-ceramic where the spatial variation in the volume fraction of high index nanocrystallites in a low index base glass can be tailored results in a transparent GRIN effective medium, as illustrated in Fig. 6(a)–(c) (Richardson, 2018; Richardson *et al.*, 2016; Kang *et al.*, 2020a,b). This technique provides a novel method to both miniaturize and enhance current IR components over that realized solely on homogeneous, single phase spherical or aspherical lenses thereby enabling a flat lens with a low chromatic aberration and a substantially reduced SWaP.

Bulk GRIN Materials

Recently, it has been reported that GeSe₂–As₂Se₃–PbSe (GAP–Se) ChGs with PbSe content of ~10–45 mol% in their bulk form are spontaneously separated into Pb-rich and Pb-deficient amorphous phases upon standard melt-quench protocol, as shown in Fig. 7(a) and (b) (Goncalves *et al.*, 2018). The energetically-favorable route to phase separation consistently seen in this material system has gained interest from optical designers and glass scientists since the Pb-rich amorphous phases, once thermally treated, can be exclusively converted into nanocrystallites with an index greater than that of the surrounding matrix. This matrix remains amorphous, as evidenced by bright and dark field (BF and DF) transmission electron microscope (TEM) images in Fig. 7(c) (Kang *et al.*, 2020a,b; Francois-Saint-Cyr *et al.*, 2019). Specifically, a DF TEM image collected from a base glass with PbSe content of 20 mol% shows sub-wavelength, amorphous secondary phases within an amorphous matrix, as indicated by the bright, circular phases in a dark matrix. The contrast between the secondary phases and the matrix in the DF TEM image suggests that the atomic percentage of heavy constituents in the secondary phases is greater than that in the matrix while the entire nanocomposite remains amorphous. A heat treatment of the base glass with PbSe content of 20 mol% selectively crystallizes the Pb-rich secondary phases, thereby generating high-refractive index nanocrystallites, as indicated by asymmetric shapes of the secondary phases in the DF TEM image. The crystalline fringes existing exclusively within the dark, secondary phases in the high-resolution BF TEM image coherently indicate the emergence of Pb-containing nanocrystals. An increase in the content of PbSe to 40 mol% and a subsequent heat treatment of the composition in the immiscibility zone induces inverse microstructures of the pre- and post-annealed GAP–Se glass with 20 mol% of PbSe. This indicates that the effective index of nanocomposites increases upon heat treatment, while maintaining their transparency as an effective medium. Since the number density and the crystallinity of the high-refractive index, Pb-rich phases can be controlled by knowledge of the nucleation and growth rates of these phases, and thus a prescribed thermal treatment protocol, a combination of the material chemistry and the process leads to our demonstration of a promising method to create a GRIN within a single component. This has been experimentally validated through the use of a gradient heat (growth step) treatment to create a varying number density of Pb-rich phases where the extent of their crystallinity, size, and volume fraction within a glass matrix enables one to spatially tune the effective index of the nanocomposite, as shown in Fig. 7(d) (Kang *et al.*, 2020a,b).

Planar GRIN Materials

The GAP–Se material system with lower dimensions has been promising due to its versatility of integration into multi-component structures such as conformal coating as well as its ability to form high refractive index phases. During a thermal evaporation process which has been widely used to deposit ChG films, source materials are condensed on a room temperature or cold substrate. As the

thermal history in the deposition is energetic, the structure of deposited films remains far from equilibrium and do not typically undergo phase separation upon their deposition; i.e., it remains amorphous with a high concentration of molecular clusters with strained bonds, thereby lowering the activation energy required to transform them to a more stable configuration (Kang *et al.*, 2018a,b, 2019; Mingareev *et al.*, 2019; Mingareev *et al.*, 2020). Therefore, the as-deposited films are energetically metastable and sensitive to external stimulation such as laser exposure and thermal treatment. It has been reported that laser exposure with a wavelength near the optical bandgap energy of the film induces the otherwise homogeneous amorphous structure to be transformed into Pb-rich amorphous phases within a Pb-deficient amorphous matrix (Kang *et al.*, 2018a,b, 2019; Mingareev *et al.*, 2019, 2020). Since the laser exposure-induced Pb-rich amorphous phase is energetically unstable, post heat treatment leads to the conversion of the amorphous phase into Pb-rich nanocrystals with a refractive index far greater than that of the Pb-deficient matrix which still remains amorphous, as shown in Fig. 8(a) (Kang *et al.*, 2018a,b). It has been shown that laser exposure can be locally controlled and the laser fluence (power density $\times$ time) dictates the number density of Pb-rich amorphous phases which subsequently become high refractive index nanocrystals upon heat treatment, as illustrated in Fig. 8(b) (Kang *et al.*, 2018a,b). The effective refractive index (n_{eff}) of the resulting GC nanocomposite films increases with the volume fraction of the high refractive index nanocrystals. The nanocomposite film's n_{eff} can be approximated by the following equation (Kang *et al.*, 2020a,b):

$$n_{\text{eff}} \approx V_{\text{matrix}} \times n_{\text{matrix}} + \sum_{i=1}^N (V_{i,\text{secondary phase}} \times n_{i,\text{secondary phase}})$$

where n and V correspond to the refractive index and the volume fraction of the nanocomposite's phases, respectively. Fig. 8(c) shows that the novel photo-thermal process has been utilized to induce spatially-controlled crystallization within GAP-Se films, thereby realizing a GRIN component such as a diffraction grating structure (Kang *et al.*, 2018a,b).

Low-Loss Waveguides

Reduction in the ChG material's dimension lends unique nature and planar system design opportunities to the device system. Due to their excellent light confinement, large refractive index, and broadband optical transparency, ChGs such as As_2S_3 and Ge-Sb-S have been actively utilized as optical waveguides, resonators, and interface layers in multi-material micro-phonic systems (Serna *et al.*, 2018; Du *et al.*, 2016; Hu *et al.*, 2007; Xia *et al.*, 2010). Furthermore, their exceptionally high nonlinearity and low multiphoton absorption are ideal for all optical signal processing, allowing ChG-based waveguides to be a core building block of integrated optical circuits (Musgraves *et al.*, 2011). Meanwhile, the most important functionality of waveguides is signal transport with minimum optical loss which has been shown to be as low as a few tenths of dB/cm in some ChG films. One of major sources for the loss is due to optical scattering which can occur from fabrication defects such as sidewall roughness, or where waveguides bend. This phenomenon is presented in a recent work where a series of As_2S_3 waveguides with different bend radii were tested to quantify the optical loss at the bending point, as shown in Fig. 9(a)–(c) (Xia *et al.*, 2010). Here, the bend waveguide simulation clearly indicates that the optical loss increases exponentially with decreasing bend radius (i.e., increasing curvature of the waveguide). To mitigate this issue, the addition of a GRIN structure to a bending point of a waveguide has been proposed, as shown in Fig. 9(d)–(f) where electric (E_z) and magnetic (H_z) field components of a wave propagating along a silica-based waveguide are observed to maintain their intensities and be confined within the waveguide (Cao *et al.*, 2017).

Optical Nonlinearity

Nonlinear Optical Property Measurements in ChG

The optical nonlinearity of a material significantly depends on the intensity of incident light which in turn is determined by a spacing between a laser beam source and a target material. The z-scan technique utilizes the phenomenon where a target sample is moved along the z-axis to vary incident beam intensity and extract its nonlinear optical parameters, as illustrated in

Fig. 9 (a) a SEM image of As_2S_3 waveguides on LiNbO_3 substrates, (b) an optical image of the waveguides with different bend radii, (c) optical loss based on bend waveguide simulations, (d) a GRIN structure in silica-based bend waveguides, (e) E_z of the waveguide in TE_0 mode, and (f) H_z of the waveguide in TE_0 mode. Fig. 10 A schematic of z-scan measurement configuration.

Fig. 10 (Sheik-Bahae *et al.*, 1989, 1991). Specifically, the z-scan technique is used to measure the nonlinear refractive index (n_2) and the nonlinear absorption coefficient (α) to measure both real and imaginary components of the optical nonlinearity. For n_2 , a closed-aperture configuration is used. The sample is placed in the focal plane of the lens, and then moved along the (axial) z axis direction, defined by the Rayleigh length. Since the target material reacts like a weak z-dependent lens in this configuration, the far-field aperture makes it possible to detect small distortions in the original beam. The focusing power of this weak nonlinear lens depends on n_2 , and therefore it is possible to extract its value by analyzing the z-dependent data acquired by the detector. For α , an open-aperture configuration is used. Specifically, the far-field aperture is removed and the whole signal is measured by the detector. In the whole signal, the small distortions in the original beam are insignificant and the z-dependent signal variation becomes dominant due to the nonlinear multi-photon absorption.

Z-scan is the most common method that has been used to measure n_2 and α for optical materials across a broad spectral window, though new techniques, such as D-scan (Serna *et al.*, 2019, 2018), have been developed for materials in other forms (i.e., planar thin films). Extension of these methods to the spectral window of use relies on an appropriate experimental set up (source/detector) and measurement away from the wavelength of resonance (typically defined as $h\nu/2$, where $h\nu$ is the optical bandgap

Fig. 11 Closed- and open-modes 4.6 μm z-scan profiles of $\text{Ge}_{23}\text{Sb}_7\text{S}_{70}$ bulk glasses. Reproduced with permission from Sohn, B.-U., Kang, M., Choi, J., *et al.*, 2019. energy of the media under test). **Fig. 11** shows representative closed- and open-modes z-scan profiles collected from $\text{Ge}_{23}\text{Sb}_7\text{S}_{70}$ bulk glasses (Sohn *et al.*, 2019). Each set of data includes two types of z-scan measurements including closed and open modes. The z-scan data in the closed mode are fitted with the following equation (Sohn *et al.*, 2017; Wang *et al.*, 2017; Bristow *et al.*, 2007; Kato *et al.*, 1995; Gholami *et al.*, 2011):

$$T_{CA} = 1 + \frac{4\Delta\varphi_0\left(\frac{z}{z_0}\right)}{\left[1 + \left(\frac{z}{z_0}\right)^2\right]\left[9 + \left(\frac{z}{z_0}\right)^2\right]}$$

where T_{CA} , $\Delta\varphi_0$, z , and z_0 are normalized transmittance in a closed-aperture mode, nonlinear refraction-induced phase change of the laser beam, sample location, and Rayleigh length, respectively. Values of $\Delta\varphi_0$ extracted from a fitted curve are then inserted in the following equation to extract values of nonlinear refractive indices:

$$n_2 = \frac{\Delta\varphi_0\lambda}{2\pi I_{00}L_{\text{eff}}}$$

where λ , I_{00} , and L_{eff} are laser wavelength, peak intensity, and effective path length for multiphoton absorption, respectively. The z-scan data in the open mode are fitted with the following equation (Sohn *et al.*, 2017; Wang *et al.*, 2017; Bristow *et al.*, 2007; Kato *et al.*, 1995; Gholami *et al.*, 2011):

$$T_{OA(nPA)} = \frac{1}{\left\{1 + (n-1)\alpha_n L_{\text{eff}} \left[\frac{I_{00}}{1 + \left(\frac{z}{z_0}\right)^2} \right]^{n-1} \right\}^{\frac{1}{n-1}}}}$$

where $T_{OA(nPA)}$, n , α_n correspond to normalized transmittance in an open-aperture mode, integer, and multiphoton absorption coefficient, respectively.

MWIR and LWIR Supercontinuum Generation in ChGs

Here, recent progress on Ge-Sb-S and Ge-Te-AgI based ChGs is introduced as model component behaviors to illustrate compositional variation on optical performance and other variation when formed into fiber. Among ChGs with wide transparency window and large refractive index facilitating mode confinement and bandgap engineering for photonic devices, Ge-based glasses with heavy metal oxide create smaller multiphoton spectra for laser and fiber optic applications (Fuxi, 1992). This phenomenon has necessitated the investigation of Ge-based ternary system's compositional dependence on its optical properties. $\text{Ge}_{23}\text{Sb}_7\text{S}_{70}$ has been demonstrated as one of the promising waveguide materials due to its radiation resistance and lower environmental toxicity as compared to As-based ChGs as well as its broadband optical transparency far into the MWIR spectral region and large optical nonlinearities (Vahalova *et al.*, 2000; Petit *et al.*, 2006; Asami *et al.*, 1997). A recent study utilizes $\text{Ge}_{23}\text{Sb}_7\text{S}_{70}$ waveguides to demonstrate supercontinuum (SC) generation (Choi *et al.*, 2016). **Fig. 12(a)** shows a schematic of $\text{Ge}_{23}\text{Sb}_7\text{S}_{70}$ ridge waveguide fabricated on a SiO_2 substrate where the films were deposited into a patterned substrate using thermal evaporation and tapers at input and output ports in the waveguide to facilitate fiber-waveguide coupling (Choi *et al.*, 2016). To see the evolution of SC generation as a function of input laser peak power (P_{peak}), a femtosecond fiber laser was guided into the $\text{Ge}_{23}\text{Sb}_7\text{S}_{70}$ waveguide. The resulting spectrum broadens from 130 to 320–510–840 nm at -30 dB level as P_{peak} increases from 120 to 220–280–340 W, respectively, as shown in **Fig. 12(b)** (Choi *et al.*, 2016). The remarkably large spectral broadening of 900 nm shows that GeSbS waveguides with a relatively large nonlinear parameter and negligible nonlinear losses could be a promising platform for

Fig. 12 (a) Schematic of Ge₂₃Sb₇S₇₀ waveguide (sky color: SiO₂ substrate, light green color: Ge₂₃Sb₇S₇₀ film), (b) output SC spectrum in Ge₂₃Sb₇S₇₀ waveguide as a function of input peak power, (c) multiphoton absorption coefficients of Ge₂₃Sb₇S₇₀ bulk glasses in the range 1.1–5.5 μm, (d) photoluminescence of Ge₂₃Sb₇S₇₀ bulk glasses induced by four-photon absorption. (e) experimental SC spectra pumped at 6, 7, and 8 μm in a step-index fiber consisting of (Ge₁₀Te₄₃)₉₀-(AgI)₁₀ core with two claddings including (Ge₁₀Te₄₀)₉₀-(AgI)₁₀ and Ge₁₀Sb₁₀Se₈₀. nonlinear optics applications at telecommunication wavelengths. Meanwhile, despite the implications from the nonlinear figure of merit, it is not always the case that the real part of the nonlinear susceptibility is the only factor worth maximizing for optical applications. The imaginary part of the nonlinear susceptibility is likewise important in that it can be utilized for photodetection, nonlinearly generated light sources, and band-structure identification (Sohn *et al.*, 2019; Zhao *et al.*, 2017). In this context, multiphoton absorption behavior and resulting photoluminescence (PL) of Ge₂₃Sb₇S₇₀ bulk glasses have been recently studied as shown in Fig. 12(c) and (d). Fig. 12(c) shows up to eleven-photon absorptions which is by far the highest order multiphoton absorption experimentally recorded to date (Sohn *et al.*, 2019). Such understanding of inter-band gap energy transition levels is crucial in applications such as SC or high harmonic generation where high pump intensities are required, since sub-bandgap excitation wavelength is much preferred to avoid any radiation-induced structural modification. Fig. 12(d) shows the PL signal observed between 1.1 and 1.68 μm, with its intensity increasing with the incident pump power (Sohn *et al.*, 2019). The slope obtained between the PL signal and input intensity was extracted to be 3.9, which is very close to the integer 4, implying that the PL is associated with four-photon absorption. The results pave the way towards new photonic device design leveraging very high order multiphoton absorption effects and multiphoton-excited PL. Meanwhile, the replacement of a light element for a heavier one typically enhances the optical nonlinearity of the materials (Wang, 2014) and broadens their optical transparency window (Wilhelm *et al.*, 2007). Especially, telluride glasses have been reported to possess the highest optical nonlinearity and broadest transmission window (Wilhelm *et al.*, 2007). Also, Se–Se induced multiphoton absorption, known to limit the broadening of SC spectra of telluride glasses, has been overcome by several candidate systems such as Ge–Te–I (Wilhelm *et al.*, 2007), Ge–Ga–Te (Danto *et al.*, 2006), and Ge–Te–AgI (Wang *et al.*, 2012; Conseil *et al.*, 2012) without containing Se. For iodine-containing tellurides, the high atomic weight of iodine allows the glass matrix's low phonon character to be maintained, thereby retaining the far-IR transparency. Furthermore, the nonlinearity of tellurides has been known to be further improved by doping with Cu or Ag (Ogusu and Shinkawa, 2009) and, based upon aforementioned findings, the Ge–Te–AgI glass system has been promising for fiber drawing and SC generation in the MWIR. Fig. 12(e) shows SC spectra excited by different pump wavelengths at 6, 7, and 8 μm in a (Ge₁₀Te₄₃)₉₀-(AgI)₁₀ fiber (Zhao *et al.*, 2017). At each pumping wavelength, the SC spectrum broadens as the pump power increases. The SC spectra are extended to 14.5, 16, and 15.4 μm under maximum pump power at different pump wavelengths of 6,

Table 1 Experimental MWIR SC generation in the ChG fiber (more than 12 μm)

Fiber	Fiber length (cm)	ZDW (μm)	Pump wavelength (μm)	SC bandwidth (μm)
As-Se	8.5	5.83	6.3	1.4–13.3 (30 dB)
As-Se	3	5.5	9.8	2–15.1 (–)
Ge-Sb-Se	20	5.5	6	1.8–14 (–)
Ge-As-Se-Te	23	10.5	4.5	1.5–14 (30 dB)
Ge-Te-AgI	14	10.5	7	2–16 (40 dB)

7, and 8 μm , respectively. **Table 1** tabulates the experimental SC data generated in a variety of ChG fibers where Te-based fibers have a broader transparent window than other ChG fibers, making them suitable for SC generation in the MWIR (Zhao *et al.*, 2017).

Summary

The key material attributes of chalcogenide glass and glass ceramic materials aimed at enabling their use in a variety of IR applications is presented. The ability to control and utilize the glass' composition, microstructure (where a glass ceramic is formed), and the material's resulting optical properties in bulk, film, fiber, and waveguide forms is reviewed. Also discussed are lingering issues that remain as challenges to the community in translating these glasses into these forms, including relevant microstructural and optical metrology methods which have been used to assess them. The effort and progress made by the glass science and engineering community as well as the optical design and fabrication "users" of the glasses has advanced considerably since the turn of the century. These efforts will likely continue as researchers and manufacturers evaluate and develop strategies to further optimize properties suitable for higher volume applications. Such work will enable chalcogenide glasses for use in a diverse range of applications and highlight the promising future of these novel materials in next generation optical systems and beyond.

Glasses: Oxynitride Glass Formation and Structure

Stuart Hampshire, The Bernal Institute, University of Limerick, Limerick, Ireland

Introduction

In modern industrial sectors, such as microelectronics, optoelectronics, communications technologies and biomedical devices, research continues to find useful lighter, stiffer materials, including glasses, with superior mechanical properties such as higher elastic moduli, hardness, strength and fracture toughness. The replacement of some of the oxygen atoms by nitrogen in oxide glasses (principally silicates, aluminosilicates and phosphates) leads to definite improvements in these properties and changes in thermal and other properties as a result of extra cross-linking of the glass network when nitrogen substitutes for oxygen.

The preparation, structure and properties of these oxynitride glasses have been extensively studied and some success has been achieved in understanding how changes in glass composition affect structural parameters and their relationship to properties. A number of reviews of oxynitride glasses have been published (Hampshire, 1993; Leng-Ward and Lewis, 1989; Sakka, 1995; Hampshire, 2003, 2008; Pomeroy and Hampshire, 2008; Becher *et al.*, 2011).

Early Research on Nitrogen Solubility in Commercial Glasses

Seeds or small bubbles caused by gaseous inclusions are always problematic in glass manufacture, particularly for optical glasses. It was shown (Todd, 1956; Neerman and Bryan, 1959) that often these defects consisted mainly of nitrogen. Mulfinger and Meyer (1963) and Mulfinger (1966) reported on the first investigations of physical and chemical solubilities of gaseous nitrogen in soda-lime-silica glasses and how this related to inclusions encountered in glass manufacture. The physical solubility of nitrogen in these glasses was found to be extremely low after bubbling nitrogen gas through the glass melt at 1400°C for 16 h.

By melting the glass in a gas furnace under reducing conditions, 10 times more nitrogen is dissolved than with the physical solubility. In strongly reducing atmospheres considerably more nitrogen is chemically dissolved (between 100 and 10⁴ times that of the physical solubility). If ammonia gas is bubbled through the glass melt at 1400°C for 5 h the chemical solubility of nitrogen in the glass reaches 0.33 wt.%, a value more than 10⁵ times higher than that for physical solubility. Mulfinger (1966) proposed that nitrogen substitutes for oxygen in the SiO₄ tetrahedra within the silicate network when conditions are reducing. This substitution leads to a higher than average coordination of non-metal atoms as in:

Fig. 1 shows a simple representation of a nitrogen atom bonded to three SiO₄ tetrahedra in a silicate glass. This results in increased crosslinking and, hence, a more rigid glass network.

Elmer and Nordberg (1967) introduced ten times as much nitrogen (3 wt.%) into a porous borosilicate glass, used as high-energy lamp envelopes, by heating in ammonia. Significant changes in properties of the glass were observed: increases in indentation hardness and electrical resistivity, and a decrease in thermal expansion coefficient. In this case, the changes observed in the physical properties of the glass resulted from the incorporation of nitrogen into the glass structure as hypothesized by Mulfinger (1966). A higher annealing temperature was required for these nitrogen-containing glasses. Normally for the borosilicate glass, devitrification could be induced electrolytically as a result of concentration of alkali ions at the cathode caused by their migration under the influence of the electric field. However, it was reported that the nitrogen-containing glasses did not crystallize as easily, thought to be due to increased viscosity, because of the presence of (=NH) and (=N-) groups.

Harding and Ryder (1970) introduced small concentrations of nitrogen into a commercial container glass batch using silicon nitride and reported increased softening temperature, viscosity and resistance to devitrification.

Davies and Meherali (1971) measured the equilibrium solubility of nitrogen in aluminosilicate melts (<38 mol.% SiO₂) similar in composition to many blast furnace slags. They found that severe reducing conditions had to be imposed in order to dissolve significant amounts of nitrogen into these melts and concluded that the solubility of nitrogen was chemical rather than physical increasing with increasing basicity, indicating that bridging rather than non-bridging oxygen atoms in the aluminosilicate glass structure were involved in the exchange reaction.

Dancy and Janssen (1976) compared physical and chemical methods of incorporating nitrogen into CaO-SiO₂-Al₂O₃ metallurgical slag melts under reducing conditions. In the presence of graphite, the solubility of nitrogen increases as a function of

Fig. 1 Representative structure showing a tri-coordinated nitrogen atom bonded to three SiO_4 tetrahedra in an oxynitride glass.

the CaO content and inversely with the SiO_2 content. The solubility is between 0.25 and 2.5 wt.% N after 24 h at 1550°C and varies with temperature, whereas, when Si_3N_4 was added to the melt (under N_2), nitrogen incorporation was very rapid and reached significantly higher levels (4 wt.%). It was suggested that most silicate melts are not significantly reducing enough to dissolve N_2 to any great extent and that it was necessary to dissolve nitrogen from nitride compounds such as silicon nitride.

Substitution of Nitrogen Into Silicates and Aluminosilicates

In all silicates, the fundamental structural unit consists of a central Si atom surrounded by 4 oxygen atoms at the corners of a tetrahedron – SiO_4 – carrying 4 negative charges. The tetrahedra share oxygen corners to form rings, chains, 2-dimensional sheets or 3-D networks. The AlO_4 tetrahedron with 5 negative charges is approximately the same size as SiO_4 and so it can replace the SiO_4 tetrahedron without structural change provided that electrical neutrality is maintained by the presence of other cations (e.g., Na, Ca, Mg, etc).

Wild *et al.* (1968) reported on crystal structure determination of α and β silicon nitrides in which the local atomic arrangement is a tetrahedral array of N atoms around a central Si atom, similar to the SiO_4 tetrahedron within silicates. A surprising result was that in α - Si_3N_4 about 1 in 30 N atoms are replaced by O atoms with compensating cation vacancies. They argued that it should be possible to replace much more N by O, which could be done by simultaneously replacing Si^{4+} by Al^{3+} to maintain the charge balance and had predicted that there was “a good possibility of developing a completely new range of nitride and oxynitride materials – vitreous as well as crystalline – based on the Si-Al-O-N system.” This led to the discovery that up to 65% Al_2O_3 could be reacted with silicon nitride to form an expanded β - Si_3N_4 solid solution – β' -SiALON (Jack and Wilson, 1972) and the proposal that nitrogen could be easily incorporated into the network of silicate and aluminosilicate glasses (Jack, 1976).

During this period, major interest was shown in silicon nitride and how it could be sintered to full density. One problem is that its self-diffusivity is quite low and atomic species only become sufficiently mobile for densification at temperatures where the decomposition of silicon nitride commences ($\sim 1850^\circ\text{C}$). Initial investigations (Lumby and Coe, 1970) involved hot-pressing α - Si_3N_4 with MgO at temperatures up to 1750°C which resulted in materials with much higher strengths than previously found. Wild *et al.* (1972) investigated the role of MgO in hot-pressing showing that it reacts with the surface silica always present on Si_3N_4 particles and at temperatures above 1400°C it forms a liquid into which some nitrogen is incorporated and this cools to give a magnesium silicon oxynitride glass as shown by subsequent divitrification to form enstatite (MgSiO_3) and silicon oxynitride ($\text{Si}_2\text{N}_2\text{O}$). As hot-pressing is restricted to simple shapes, this is a serious disadvantage for more complicated components. It was subsequently found that a combination of Y_2O_3 and Al_2O_3 additives (Tsuge and Nishida, 1978) provided the necessary conditions for pressureless liquid phase sintering (Hampshire and Jack, 1981) with the formation of an intergranular Y-Si-Al-O-N glass phase on cooling.

As progress was made in understanding the nature of silicon nitride ceramics (Riley, 2000; Lange, 2006; Hampshire, 2009), how additive chemistry controlled microstructure and how microstructure affected properties (Becher *et al.*, 1998; Sun *et al.*, 1998), there was a growing impetus to understand the nature of these intergranular oxynitride glass phases. This resulted in a number of investigations, as outlined below, of oxynitride glass formation, structure, properties and crystallization in various M-Si-O-N, M-Si-Al-O-N and M-Si-Mg-O-N systems, where M is a modifying cation such as Mg, Ca, Ba, Sc, Y and the rare earth lanthanides.

Preparation of Si-Based Oxynitride Glasses

Oxynitride glasses have conventionally been synthesized by mixing the appropriate powders – silica, alumina, the modifying oxide(s) plus silicon nitride or aluminum nitride – in isopropyl alcohol in a ball mill, followed by evaporation of the alcohol. Compacts of the mixtures (up to 100 g) are melted in boron nitride lined graphite crucibles under 0.1 MPa nitrogen pressure at temperatures in the range 1650 – 1750°C for 1 h, after which the crucible is quickly removed from the furnace and poured into a preheated graphite mold at ~ 850 – 900°C . The glass is annealed close to its glass transition temperature (T_g) for one hour to

remove stresses and then slowly cooled (Hampshire *et al.*, 1994; Hampshire, 2008). Glasses that have been prepared by this route have been studied most extensively.

The upper limit for firing temperatures is determined by thermal decomposition of Si_3N_4 , whereas the lower limit is set by the temperature for complete melting of the particular composition. Oxynitride melts have higher viscosities than their oxide equivalents at these temperatures (Hampshire *et al.*, 1985). The temperature must thus be high enough to give the melt a fluidity that ensures good homogenization, but low enough to avoid decomposition reactions.

The main difficulties encountered in the preparation of oxynitride glasses are the fairly high melting temperatures, the requirement for a low oxygen partial pressure during melting, to avoid oxidation of glass forming components, and also the limited number of nitride compounds to be used as the source of nitrogen. All investigators found that viscosity increases with N content (Hampshire and Pomeroy, 2004). There are also a limited number of non-reactive crucible materials with oxides reacting too easily with oxynitride melt compositions and platinum or molybdenum also reacting under reducing conditions. Hence the use of BN or BN-coated graphite crucibles.

Oxynitride glasses can also be prepared by melting mixtures of a pure metal or the metal hydride with silica and silicon nitride under a N_2 atmosphere which has enabled the preparation of oxynitride glasses with significantly higher concentrations of nitrogen up to 18–20 at.% (Hakeem *et al.*, 2005; Sharafat *et al.*, 2008, 2009).

Oxynitride glasses have also been prepared at lower temperatures by using sol-gel techniques (Brinker and Haaland, 1983; Brow and Pantano, 1984a) in which oxide gels are converted to oxynitride gels by treatment with flowing anhydrous ammonia at temperatures in the range 700–1100°C. Brinker and Haaland (1983) synthesized dense, colorless and homogeneous glasses in the Na-Al-Ba-Si-O-N system.

Elemental losses have been reported to occur, to a varying degree, during the preparation of oxynitride glasses above $\sim 1550^\circ\text{C}$. Loehman (1985) compared the relative oxidation or reduction tendencies of possible reactions occurring in oxynitride melts using standard Gibbs energies (ΔG°) plotted as functions of temperature on an Ellingham diagram. The positions of the ΔG° versus T plots for the following oxidation reactions (1) and (2) allow the stabilities of melts containing Si_3N_4 or AlN and various oxides to be determined:

Modifier (M) oxides such as MgO , CaO , Al_2O_3 , Y_2O_3 and Li_2O have ΔG° values which are more negative than ΔG° for oxidation of Si_3N_4 or AlN and thus are stable in M-Si-Al-O-N melts under reducing conditions whereas oxides such as Na_2O , K_2O , B_2O_3 and P_2O_5 have ΔG° values which are more positive and thus they are reduced and the nitrides are oxidized. Jankowski and Risbud (1983) prepared compositions in the Si-Ca-Al-B-O-N system but were only able to form glasses when the B_2O_3 content of the batch was less than ~ 3 wt.%, otherwise weight losses were high causing bubbles. Coon *et al.* (1983) reported substantial losses of B_2O_3 and Na_2O on melting N-containing borosilicate glasses.

Frischat and Schrimpf (1980) reported that only about 80% of the initial amount of N was incorporated into a Na_2O -CaO- SiO_2 glass when N was added as Si_3N_4 . Bachar *et al.* (2012) reported similar results for incorporation of N from Si_3N_4 into Na_2O -CaO- SiO_2 bioactive glass compositions. Many reports of significant weight losses during melting are concerned mainly with M-Si-O-N glasses (without Al) where M is an alkali metal such as Na or K. During melting under reducing conditions, silica dissociates to form divalent Si as $\text{SiO}(\text{g})$ or liquid Si (which forms colloidal precipitates in the glass on cooling) according to (Sharafat *et al.*, 2015):

The partial pressure of SiO, the gaseous product from these reactions, at temperatures of $\sim 1700^\circ\text{C}$ is high enough to account for the losses observed. In reactions (3) and (5), elemental Si is formed in the melt and loss of SiO occurs along with N_2 in reactions (4) and (6). This loss along with loss of a small amount of the modifier also occurs when preparing nitrogen rich glasses in AE-Si-O-N (AE = Mg, Ca, Sr, Ba) systems (Sharafat *et al.*, 2008, 2009). The losses were found to increase with higher concentrations of nitrogen in the starting mixture and also with increasing temperature. Glasses containing Al in various M-Si-Al-O-N systems tend to exhibit much lower weight losses.

One consequence of the formation of the elemental Si in oxynitride glasses is the dark color and lack of transparency. Messier and Deguire (1984) ascribed the dark color in Y-Si-Al-O-N glasses to the presence of Si-rich metallic precipitates caused by thermal decomposition during processing. They found that glasses, prepared using AlN as the nitrogen source, were much more transparent than those prepared using Si_3N_4 . Korgul and Thompson (1993) showed that lack of transparency was associated with dark precipitates in Mg-Si-Al-O-N and Y-Si-Al-O-N glasses and analysis confirmed that they contained Si and FeSi_2 , formed by reaction of Fe impurities, present in the initial powders, with Si_3N_4 . However, glasses prepared using AlN as the nitrogen source did not exhibit better transparency.

Fig. 2 The four-component Si-Al-O-N system showing the solid phases which exist: β' -SiAlON and its range of solid solution, O', X-phase, sialon polytypoids and a small area of glass (G).

Glass Formation in Oxynitride Systems and Their Representation

Jack (1977) explored glass formation in the MgO-SiO₂-AlN and Y₂O₃-SiO₂-AlN ternary systems and reported up to 10 at.% N for Mg-Si-Al-O-N glasses and 12 at.%N for Y-Si-Al-O-N glasses. Loehman (1979) also investigated the Y₂O₃-SiO₂-AlN ternary system. Glasses were prepared with up to 7 at.% N. Pastuszak and Verdier (1983) determined the glass formation in different M_xO_y-SiO₂-AlN ternary systems where M = Mg, Ca, Ba, Mn, Nd. Messier and Gleisner (1988) explored the glass forming region in the Li₂O-SiO₂-AlN ternary and reported up to 9 at.% N in one composition. Rocherulle *et al.* (1989a) investigated the Gd₂O₃-SiO₂-AlN and Nd₂O₃-SiO₂-AlN ternary systems in which small regions of glass formation were found with nitrogen contents of 2 wt.%. Rocherulle *et al.* (1989b) determined the extent of oxynitride glass regions within Li-Si-Al-O-N and Li-Si-O-N systems. Murakami *et al.* (1995) investigated the Yb₂O₃-AlN-SiO₂ ternary system and reported glass formation in the range 30–50 mol.% AlN, 30–50 mol.% Yb₂O₃ and 50–70 mol.% SiO₂ after melting at 1550°C.

The problem with a simple ternary representation is that it is insufficient to cover all possible compositions. As oxynitride glasses in various M-Si-Al-O-N systems are synthesized from five components: SiO₂, Al₂O₃, Si₃N₄, AlN, and the modifying oxide (s), an alternative approach is based on reciprocal salt systems (Findlay, 1927; Zernicke, 1955) which consist of two or three cations and two anions. The compositions are expressed in equivalent percent (eq.%) of cations and anions instead of atomic, molar or weight percentages (Jack, 1976; Gauckler *et al.*, 1978). One equivalent of any element always reacts with one equivalent of any other element or species.

The four-component Si-Al-O-N system (see Jack, 1991) is a square plane which has, as components, the oxides and nitrides of silicon and aluminum as shown in Fig. 2. In this system, it is convenient to let the bottom left hand corner of the square represent one mole of Si₃N₄ with 12 +ve and 12 -ve valencies. The other corners of the square represent Al₄N₄, Al₄O₆ and Si₃O₆. In going from left to right, 3Si⁴⁺ is gradually replaced by 4Al³⁺ and from bottom to top 4N³⁻ is replaced by 6O²⁻. Fig. 2 shows the solid phases which are known to exist in this system but not the compatibility and phase relationships. The main phase of interest is the β' -SiAlON solid solution (Jack and Wilson, 1972; Jack, 1976) with a range of compositions: β' -Si_{6-z}Al_zO_zN_{8-z} where $z = 0$ is Si₃N₄ and the limit of solid solution is approximately $\beta'_{z=4.2}$. Silicon oxynitride, Si₂N₂O also has a limited range of solid solution (marked O'). The liquid region at 1700°C in the SiO₂-rich corner is quite extensive (Jack, 1991) but there is only a very limited glass forming region (marked G) and very rapid quenching is required (Roebuck, 1978; see also Leng-Ward and Lewis, 1989). Other phases in this system are X-phase and sialon polytypoids (8H, 15R, 12H, 21R, 27R and 2H⁶) with structures based on that of wurtzite-type AlN (Thompson *et al.*, 1983).

Any point in the square represents a combination of 12 positive and 12 negative valence units. The cations and anions are thus treated separately. The concentrations can be expressed as equivalent percentages (eq.%) of either cations or anions as follows:

$$\text{equivalent percentage (eq.\%) Si} = (4[\text{Si}] \times 100) / (4[\text{Si}] + 3[\text{Al}]) \quad (7)$$

where [Si] and [Al] are, respectively, the atomic concentrations of Si and Al in any composition and 4 and 3 are their respective normal valencies.

$$\text{equivalent \% (eq.\%) Al} = 100 - \text{eq.\% Si} \quad (8)$$

For the anions:

$$\text{equivalent \% (eq.\%) of nitrogen} = (3[\text{N}] \times 100) / (2[\text{O}] + 3[\text{N}]) \quad (9)$$

where [O] and [N] are, respectively, the atomic concentrations of oxygen and nitrogen within any composition and 3 and 2 are their respective valencies.

$$\text{equivalent \% (eq.\%) oxygen} = 100 - \text{eq.\% N} \quad (10)$$

The introduction of a further cation gives a five-component system represented by Jänecke's triangular prism (Jänecke, 1907) shown in Fig. 3 for the Y₄O₆-Y₄N₄-Si₃N₄-Si₃O₆-Al₄N₄-Al₄O₆ (Y-Si-Al-O-N) system (see Hampshire, 2008). Any vertical plane within the prism has a constant N:O ratio.

Fig. 3 The Y-Si-Al-O-N system using Jänecke's prism representation showing the complete glass forming region and the $\text{Si}_6\text{N}_8-\beta'_{z=4.2}-\text{Y}_{1.5}\text{Al}_{2.5}\text{O}_6$ (YAG) plane on which is an area of liquid formation (L) at 1550°C. Based on data from: (a) Drew, R.A.L., Hampshire, S., Jack, K.H., 1981. Nitrogen Glasses. Proceedings of the British Ceramic Society 31, 119–132. (b) Redington, W., Redington, M., Hampshire, S., Serantoni, M., 2003. Properties of some high Al content glasses in various lanthanide–Si–Al–O–N systems. Journal of Non-Crystalline Solids 316, 74–81.

Fig. 4 Plan view of Y-Si-Al-O-N Jänecke prism showing projections of the glass forming regions at 0, 10, 16, 20 and 22 eq.% N and the $\text{Si}_6\text{N}_8-\beta'_{z=4.2}-\text{YAG}$ plane with area of liquid (L). Also shown is higher Al glass formation at 6 eq.% N (G_6) and 16 eq.% N (G_{16}). After: (a) Drew, R.A.L., Hampshire, S., Jack, K.H., 1981. Nitrogen Glasses. Proceedings of the British Ceramic Society 31, 119–132. (b) Redington, W., Redington, M., Hampshire, S. and Serantoni, M., 2003. With a modifying cation M (in this case Y) with valency v_M :

$$\text{equivalent \% (eq.\%) of M} = (v_M[M] \times 100) / (4[\text{Si}] + 3[\text{Al}] + v_M[M]) \quad (11)$$

The complete glass forming region for the Y-Si-Al-O-N system based on data of Drew *et al.* (1981) is outlined in the Jänecke prism of Fig. 3 using a computer-based drawing system developed by Redington-Keely *et al.* (2000). AutoCAD® combined with AutoLISP® allows data from multiple sources to be integrated. The colored rings represent the glass forming regions on vertical planes of 0, 10, 16, 20, 22 and 26 eq.% N (Redington *et al.*, 2003). The limit of the $\text{Y}_2\text{O}_3\text{--SiO}_2\text{--Al}_2\text{O}_3$ glass region (0 eq.% N) is shown on the oxide face of the prism and this expands initially with a larger glass forming region at 10 eq.% N. The glass forming region then diminishes becoming smaller as nitrogen content increases until the solubility limit for nitrogen is reached, in this case at ~28–30 eq.% N. The $\text{Si}_6\text{N}_8-\beta'_{z=4.2}-\text{Y}_{1.5}\text{Al}_{2.5}\text{O}_6$ (YAG) plane is also shown on which can be seen an area of liquid formation (marked L) at 1550°C indicated by Hohnke and Tien (1983).

A plan view can be seen in Fig. 4 which shows projections of the glass forming regions on the vertical planes at 0, 10, 16, 20 and 22 eq.% N (after Drew *et al.*, 1981). Also shown is the $\text{Si}_6\text{N}_8-\beta'_{z=4.2}-\text{YAG}$ plane and the area of liquid (L). Based on this, Redington *et al.* (2003) investigated higher Al content compositions and found that glass formation extended along the dashed lines up to compositions containing 56 eq.% Al at 6 eq.% N (marked G_6) and up to 54 eq.% Al at 16 eq.% N (marked G_{16}). The

Table 1 Effect of N on lowest eutectic temperatures ($^{\circ}\text{C}$) in binary silicate ($\text{M}_x\text{O}_y\text{-SiO}_2$) systems

The kinetics of densification and phase transformation in nitrogen ceramics. *Proceedings of the British Ceramic Society* 31, 37-49; Hampshire, S., Drew, R.A.L. and Jack, K.H., 1985. Oxynitride Glasses. *Physics and Chemistry of Glasses* 26, 182-186.

higher Al and N content glasses (54 eq.% Al at 16 eq.% N) were also reported for the Sm-Si-Al-O-N system while high Al (56 eq.%) glasses were reported at lower N (6 eq.%) for Y-, La-, Nd-, Sm- and Dy-Si-Al-O-N systems.

Hampshire *et al.* (1985) explored the complete glass forming region within the Mg-Si-Al-O-N Jänecke prism and glasses are formed with up to 25 eq.% N. They also show quite extensive glass formation within the Ca-Si-Al-O-N system on a vertical section equivalent to 20 eq.% N. Nd-Si-Al-O-N glasses were also prepared with similar compositions to establish comparative properties.

Loehman (1980) presented his previous results of oxynitride glass formation on the $\text{Y}_2\text{O}_3\text{-SiO}_2\text{-AlN}$ ternary plane within the $\text{Y}_4\text{O}_6\text{-Y}_4\text{N}_4\text{-Si}_3\text{N}_4\text{-Si}_3\text{O}_6\text{-Al}_4\text{N}_4\text{-Al}_4\text{O}_6$ Jänecke prism. The glass forming region within the Mg-Si-Al-O-N Jänecke prism with up to 10 at.% N was also illustrated. Loehman also showed a projection on the ternary $\text{MgO-SiO}_2\text{-Al}_2\text{O}_3$ phase diagram of the results for glass compositions containing 10 wt.% Si_3N_4 . The glass-forming region roughly corresponded to the region within the oxide ternary that is liquid at 1600°C . Compositions with high Si or low Al contents were generally phase separated or contained bubbles ("frothy") including a limited range of phase separated Mg-Si-O-N glasses. Phase separated Ca-Si-O-N glasses were prepared containing 10 wt.% Si_3N_4 and addition of ~ 5 wt.% Al_2O_3 suppresses the phase separation giving homogeneous glasses. Other glasses were prepared in the La-Si-Al-O-N and Li-Si-Al-O-N systems but no details reported (Loehman, 1980).

Jankowski and Risbud (1983) prepared compositions in the Si-Ca-Al-O-N system and glasses with nitrogen contents up to 11 at.% were formed. Tu *et al.* (1995) found a more extensive glass forming region in the Sm-Si-Al-O-N system with up to 40 eq.% N. Zhang *et al.* (1996) indicated an extensive glass forming region in the Nd-Si-Al-O-N and La-Si-Al-O-N systems.

In M-Si-O-N systems, much smaller glass-forming regions are observed which confirms the ability of Al_2O_3 to extend the range of glass formation in both silicate and oxynitride systems. The miscibility gap in various silicate binary systems extends into the equivalent M-Si-O-N system with resulting phase separation in some glasses as in the following systems: Mg-Si-O-N (Jack, 1977; Loehman, 1980; Drew *et al.*, 1981; Shaw *et al.*, 1984); Mg-Sc-Si-O-N (Tredway and Loehman, 1985); Li-Si-O-N (Wusirika and Chyung, 1980; Rocherulle *et al.*, 1989b); Ca-Si-O-N (Loehman, 1980; Hampshire *et al.*, 1985); Ce-Si-O-N (Ohashi and Hampshire, 1991); Y-Si-O-N (Ohashi *et al.*, 1995).

More homogeneous glasses with much higher nitrogen contents are possible by using a pure metal or metal hydride rather than the oxide as in the following systems: Sr-Si-O-N – Sr metal (Sharafat *et al.*, 2009) - glasses containing up to 36 eq.% Sr and 45 eq.% N; Ca-Si-O-N (Sharafat *et al.*, 2008) using CaH_2 - glasses with up to 36 eq.% Ca and 42 eq.% N; Ba-Si-O-N (Sharafat and Jonson, 2011) using BaH_2 - glasses with up to 36 eq.% Ba and 42 eq.% N.

All of these investigations of oxynitride glass formation showed that the compositional ranges which formed homogeneous glasses were more extensive than the corresponding oxide system. This can be explained by considering the melting range for the glasses. A study of the initial liquid formation temperature for mixtures of silicon nitride and metal oxides (M_xO_y) showed that the lowest solidus temperatures in the corresponding $\text{M}_x\text{O}_y\text{-SiO}_2$ system are lowered by the addition of nitrogen (Hampshire and Jack, 1981; Hampshire *et al.*, 1985) as shown in Table 1. As nitrogen increases the viscosity of the liquid, this, together with a larger melting range, increases the tendency for glass formation and suppresses crystallization.

Effect of Fluorine on Oxynitride Glass Formation

Fluorine in silicate and aluminosilicate glasses acts as a powerful network disrupter which substitutes for bridging oxygen ions (Hill *et al.*, 1999) and lowers melting temperatures. Hanifi *et al.* (2009) investigated the effects of fluorine on the extent of the original glass forming region (Hampshire *et al.*, 1985) on the $6\text{Ca}^{2+} - 3\text{Si}^{4+} - 4\text{Al}^{3+}$ ternary vertical plane in the Ca-Si-Al-O-N Jänecke prism at 20 eq.% N by substituting 5 eq.% F for oxygen. After melting compositions at 1650°C , they found that glass formation extends to more Ca-rich compositions (40–49 eq.% Ca) when F is present.

The melting endotherm temperatures were measured by differential thermal analysis (DTA) for the Ca-Si-Al-O-N-F glasses, which were found to be in the range $1150\text{--}1300^{\circ}\text{C}$. Hanifi *et al.* (2011) compared these with liquidus temperatures reported for corresponding cation ratio compositions in the $\text{CaO-Al}_2\text{O}_3\text{-SiO}_2$ ternary system (Levin *et al.*, 1964). It was found that the addition of both nitrogen and fluorine reduces the liquidus temperatures of all compositions investigated.

At low Al contents (6 eq.%), melting temperatures decrease from $1400\text{--}1430^{\circ}\text{C}$ to $1240\text{--}1270^{\circ}\text{C}$. As Ca content increases (up to 49 eq.% Ca), liquidus temperatures are too high for melting to occur at 1650°C in the oxide system but melting temperatures for the Ca-Si-Al-O-N-F glasses are in the range of $1165\text{--}1225^{\circ}\text{C}$, around 800°C lower. In the Ca-Si-Al-O-N system, compositions in

this region are not fully melted even at 1700°C and contain solid crystalline phases (Hampshire *et al.*, 1985). For the SiO₂-rich and Al₂O₃-rich compositions within the Ca-Si-Al-O-N-F glass forming region, liquidus temperatures are 100–250°C lower than their oxide equivalents. At Al contents of 30–35 eq.%, liquidus temperatures decrease from 1430–1530°C to 1265–1270°C. The melting temperature for a composition of (in eq.%): 35Ca:50Si:15Al:75O:20N:5F is reduced from 1600°C to 1240°C.

At 5 eq.% F substitution for oxygen, the solubility limit for N is ~25 eq.%. When 1 eq.% F is substituted for oxygen, the maximum nitrogen content substantially increases to 40 eq.% N at the composition (in eq.%) 28Ca:57Si:15Al:59O:40N:1F. It was concluded that fluorine affects the dissolution of nitrogen into the melt by significantly lowering the liquidus temperature. A glass with composition (in eq.%) 28Ca:57 Si:15Al:75O:20N:5F was successfully melted at 1400°C and cast into bars. It is clear that the role of fluorine is to reduce the melting range which enhances glass formation.

Oxynitride Glass Structure

The properties of glasses are a function of their structural features (Rouxel, 2007) involving short-range order, i.e., coordination number (CN), interatomic bonding, etc., and also meso-scale structures such as sheets, chains, rings, etc., made up of SiO₄ tetrahedra which are shared in three dimensions in such a way that there is a distribution of different Si-O-Si bond angles. Each oxygen corner forms a bond – a bridge – between two SiO₄ tetrahedra in the glass network and these are known as Bridging Oxygens (BO's). The number of bridging oxygens, n , per Si tetrahedron is denoted as Q^n .

Alkali metals, alkaline earths and rare earths that have a preference for ionic bonding and have higher CN's than Si serve as network modifiers (Stanworth, 1948) and they occupy interstitial sites in the network, reducing the unoccupied free volume in the structure and creating Non-Bridging Oxygens (NBO's). To maintain charge neutrality each NBO is associated with the positive charge of a nearby alkali ion. With a divalent modifier M such as Mg, Ca or Sr, every M^{2+} ion must have two neighboring NBO's and is much more tightly bonded to the silicate network, providing stronger network linkages and hence improved chemical durability and lower ionic conductivity, due to lower ion mobility through the network (Shelby, 1985).

Al^{3+} is an intermediate ion in that it can act as a glass former when combined with Si^{4+} ions. Al is generally in octahedral coordination in crystalline materials but its CN can be as low as 4 in glasses where $[AlO_4]^{5-}$ structural units replace $[SiO_4]^{4-}$ units and replacing NBO's with cross-linking Al-O-Si bonds requires charge balance of the $[AlO_4]^{5-}$ by the modifying cations. The modifier becomes a "network dwelling" ion in an interstitial site within the network. Increase in cross-linking occurs until the ratio $[Al]:1/x[M^{x+}]$ is exceeded and results in the formation of more NBO's. The Al^{3+} effectively becomes a network modifying ion in 6-fold coordination (Day and Rindone, 1962).

In much of the early literature cited above on oxynitride glass formation, many authors also presented results showing progressive changes in physical or thermal properties with increasing nitrogen content and speculated that these changes were a result of extra cross-linking as tri-coordinated nitrogen replaced di-coordinated oxygen in the glass network as first suggested by Mulfinger (1966). Structural factors that can cause changes in properties include variations in BO's versus NBO's, Si-O-N coordination, the coordination of Al and other cations with oxygen, average bond lengths, etc. Structural features of oxynitride glasses have been assessed using Fourier Transform Infrared (FTIR) and Raman spectroscopy, Nuclear Magnetic Resonance (NMR) and X-ray Photoelectron Spectroscopy (XPS).

FTIR Spectroscopy

A number of authors have reported IR absorption spectra for different oxynitride glasses: SiO₂-Si₃N₄ films (Chu *et al.*, 1968); Na₂O-SiO₂-Si₃N₄ (Brow and Pantano, 1984b); Na₂O-CaO-SiO₂-Si₃N₄ (Frischat and Schrimpf, 1983; Brow and Pantano, 1984b); Y-Si-Al-O-N (Loehman, 1979); Li-K-Si-Al-O-N (Luping *et al.*, 1983); M-Si-Al-O-N where M = Mg, Ca, Ba, Li (Videau *et al.*, 1997). The shape and position of the main absorption peak centered around 1045 cm⁻¹ in the SiO₂ and silicate spectra attributed to asymmetrical stretching vibration modes of Si-O-Si bonds shifts to lower wave numbers with increasing nitrogen content, and the merging of Si-O and Si-N bands widens the spectra. This is clear evidence for the substitution of oxygen by nitrogen in the silicate network.

Videau *et al.* (1997) analyzed IR spectra of M-Si-Al-O-N glasses, where M = Mg, Ca, Ba, Li with composition: $M_{0.37}Si_{0.53}Al_{0.1}O_{1.58-3x}/2N_x$ with x varying from 0 to 1. The IR spectra for the Mg-containing glasses is shown in Fig. 5. Increase of the nitrogen content leads to the broadening of the band in the 800–1000 cm⁻¹ absorption range with, simultaneously, an occurrence of two maxima at around 1050 and 1000 cm⁻¹ for Mg₂ to Mg₄ (increasing N). An increase of the intensity and a shift towards the lower frequencies of the absorption band is attributed to Si-O⁻ (Mg²⁺) bond vibrations for Mg₁. As N is introduced, formation of Si-N bonds involves the weakening of neighboring Si-O-(Si, Al) bonds with the appearance of: Si-N around 1050 cm⁻¹; N-Si-O...(Si) between 970 and 1000 cm⁻¹; Si-N vibrations around 950 cm⁻¹, in (N₃Si)-O-(SiN₃) molecular entities with Si-N-Si vibration modes between 850 and 950 cm⁻¹ (corresponding vibrations become overlapped with those of the Si-O⁻ (Mg²⁺) non-bridging bond).

In the 650–800 cm⁻¹ absorption range, the characteristic band at 730 cm⁻¹ for the AlO₄ tetrahedra was identified in the aluminosilicates (Mg₁ x = 0) but the characteristic band for (Al_{IV}-O) disappeared when N was introduced and evidence for the

Fig. 5 The IR spectra for glasses with compositions $\text{Mg}_{0.37}\text{Si}_{0.53}\text{Al}_{0.1}\text{O}_{1.58-3x/2}\text{N}_x$ with x varying from 0 (Mg₁) to 1 (Mg₄). After Videau, J.J., Etourneau, J., Rocherulle, J., Verdier, P., Laurent, Y., 1997. Structural approach of sialon glasses: M-Al-Si-O-N. *Journal of the European Ceramic Society* 17, 1955–1961.

presence of MgO_4 tetrahedra is shown. In Mg-Si-Al-O-N glasses, Al takes on octahedral coordination with oxygen (AlO_6) and Mg becomes a network former as more nitrogen is incorporated (Hampshire *et al.*, 1985; Videau *et al.*, 1997).

X-ray Photoelectron Spectroscopy

The XPS binding energies of an element are related to the fractional atomic charge about that element. Thus, the position of the elemental binding energy will depend on the electronegativities of neighboring elements. Elements with similar chemical environments will have similar electron binding energies.

Brow and Pantano (1984b) showed that in Na-Ca-Si-O-N glasses the primary N 1s binding energies are similar to those for crystalline Si_3N_4 , providing direct evidence for the presence of tri-coordinated nitrogen in the glass structure (see Fig. 1). It was assumed that low-energy components of the N 1s photoelectron spectra may have resulted from the presence of non-bridging nitrogen groups such as (a) $\equiv \text{Si} - \text{N}^- - \text{Si} \equiv$ and (b) $\equiv \text{Si} - \text{N}^{2-}$ shown in Fig. 6. The local charge on the non-bridging nitrogen ions is balanced by the presence of interstitial metal ions in close proximity.

Schneider *et al.* (1997) analyzed Ca-Mg-Si-Al-O-N glasses containing up to 10 at.% N by XPS. In glasses with more than 5 at.% N there was evidence for additional bondings which related to the existence of “non-cross-linked” nitrogen forming less than three covalent bonds to the network as in (a) and (b) above (Fig. 6). This means that N may bond with either a modifying cation or be left with a dangling bond. While the strength of the Si-O bond ($U_{\text{Si-O}} = 800$ kJ/mol) is seen to be stronger than for the Si-N bond ($U_{\text{Si-N}} = 437$ kJ/mol), that is Si-O has a greater stretching force constant, calculations show that the Si-N bond is more resistant to bending (Rouxel, 2007), which combined with the increased coordination with Si would increase the rigidity of the network. Bonding is much more covalent for Si-N than for Si-O so that bending is more difficult for Si-N-Si than for Si-O-Si linkages, contributing to the greater rigidity.

Solid State Magic Angle Spinning (MAS) Nuclear Magnetic Resonance (NMR)

More details of the structural aspects of oxynitride glasses were determined from solid state MAS NMR. High-resolution solid-state ^{29}Si MAS NMR spectra from inorganic materials were first obtained in 1980 and early work on oxynitride glasses using this analysis technique was carried out by Aujla *et al.* (1986). The ^{29}Si spectrum from an oxide glass of composition $\text{Y}_{1.03}\text{Si}_{1.27}\text{Al}_{1.27}\text{O}_6$ consists of one broad peak with chemical shift centered at -83 ppm but it was not possible to resolve different degrees of polymerization of this SiO_4 peak into Q^2 , Q^3 , Q^4 . When 15 eq.% N was substituted for oxygen to form a glass of composition $\text{Y}_{1.03}\text{Si}_{1.27}\text{Al}_{1.27}\text{O}_{5.1}\text{N}_{0.6}$ the spectrum was resolved into three contributing peaks centered at -83 , -71 and -60 ppm which are characteristic of SiO_4 , SiO_3N and SiO_2N_2 tetrahedral units.

Bachar *et al.* (2016) compared the ^{29}Si MAS NMR spectra of bioactive glasses with compositions (mol.%): $(55-3x)\text{SiO}_2-13.5\text{CaO}-31.5\text{Na}_2\text{O}-x\text{Si}_3\text{N}_4$ where $x = 0-4$ ($x = 4$ corresponds to 3.3 at.% N). Deconvolution analysis was carried out to

Fig. 6 Representative structures showing N-SiO₄ bonding in silicate glasses: (a) the N atom acts as a bridge between 2 SiO₄ tetrahedra, (b) Non-bridging N atoms may also be present - O₃Si-N²⁻. Charge balance is from interstitial metal cations in close proximity.

determine the contributions of different Qⁿ modes. In the spectrum of the glass without nitrogen (**Fig. 7(a)**), the main contributions in the signal are located around -78.1 and -85.3 ppm, attributed respectively to Q² (37%) and Q³ (63%) units. When nitrogen is substituted for oxygen, more Si environments appear with two new bands at around -70 and -59 ppm, attributed to SiO₃N and SiO₂N₂ units, respectively, similar to the spectra reported by Aujla *et al.* (1986). **Fig. 7(b)** shows that addition of the maximum nitrogen (3.3 at.%) results in more SiO₃N tetrahedra, fewer Q³ units and the appearance of Q⁴ units and SiO₂N₂ tetrahedra.

Glasses with composition Y_{1.03}Si_{1.27}Al_{1.27}O_{6-3x/2}N_x where x is 0.8 and 1.2 to give 20 and 28 eq.% N, respectively, were analyzed using NMR by Kruppa *et al.* (1991). The ¹⁵N spectrum of the glass indicates that there are [NSi₃] or possibly [NSi₂Al] units in the structure and also [-NSi₂] units (~20%). Further evidence that nitrogen atoms may bond to only two (or even one) Si atom was provided by Sakka (1995) who studied Na-Si-O-N and Y-Si-Al-O-N glasses by ²⁹Si, ²⁷Al and ¹⁵N MAS NMR. The average CN for N in the Na-Si-O-N glass is 2.42 which allows a simple calculation to conclude that 58% of N atoms are bonded to two Si atoms and only 42% to three Si atoms (Jin *et al.*, 1993; Sakka, 1995). Unuma *et al.* (1992) by means of MD calculations obtained CN = 2.3. In the Y-Si-Al-O-N glass, the average CN for N is 2.86 which suggests that 86% of the N atoms are 3-fold coordinated and 14% are 2-fold coordinated. The local charge on the nitrogen ions with CN < 3 is balanced by the presence of interstitial modifying cations in their local environment.

Sakka (1995) also suggested that in oxynitride glasses containing Al, Si-N bonding is preferred to Al-N bonding. Thus, as all nitrogens are preferentially bonded to silicon, it is possible to estimate the average number of nitrogens bonded to each silicon, i.e., x in each SiO_(4-x)N_x tetrahedron within the glass network. **Fig. 8** shows the variation in the average number of nitrogens per tetrahedron as a function of nitrogen content for a range of glass compositions given in **Table 2**, calculated using the formula $x = 3(x_N/x_{Si})$, where x_i represents atomic fraction of i (N or Si). It is seen that for most glasses the average number of nitrogens bonded to silicon does not exceed 1 until a nitrogen content of 15 eq.% is reached. For the B-phase glass with a higher Al:Si ratio, more than one nitrogen is bonded to silicon if the nitrogen content exceeds about 10 eq.% N.

Lofaj *et al.* (2004a) studied the effects of rare earth (RE) elements and nitrogen on the structure of RE-Si-Mg-O-N glasses (RE = Sc, Y, La, Nd, Sm, Gd, Yb and Lu) with different nitrogen contents. NMR showed that nitrogen modifies the glass structure depending on the RE by increasing the content of SiO₃N units (Qⁿ ⇒ Qⁿ⁺¹) at the expense of Q² units and this appears to be more effective in Lu-containing glasses than those with La. Despite that, the effects of rare-earth modifiers and nitrogen as a network former are independent and additive and a synergy effect was not observed.

Raman Spectroscopy

Rouxel *et al.* (1990) used Raman spectroscopy to analyze SiYAlON glasses and obtained two broad peaks, the main one at ~950 cm⁻¹ which shifted to higher wave number with increasing N content. This was assigned to a vibrational mode involving perturbed SiO₄ tetrahedral units with Si-O-Al or Si-O-Y linkages.

Dolecekic *et al.* (2007) carried out Raman spectroscopic analyses on Er-Si-Al-O-N glasses with N contents of 0, 5, 8, 15 and 22 eq.% and constant cation ratios of Er:Si:Al = 3.45:3:2. Careful deconvolution of the Raman spectra showed that Al³⁺ is in 4-fold coordination with oxygen. Also the proportion of Q³ silicate species decreases as nitrogen content increases and there is a corresponding increase in the proportion of Q⁴ (oxynitride) species, implying that a transformation occurs of the type:

shown schematically in **Fig. 9** with the extra crosslinking between individual tetrahedra.

Fig. 7 ^{29}Si MAS NMR spectra of glasses with compositions (mol.%): $(55-3x)\text{SiO}_2-13.5\text{CaO}-31.5\text{Na}_2\text{O}-x\text{Si}_3\text{N}_4$ (a) $x = 0$, (b) $x = 4$, corresponds to 3.3 at.% N showing deconvolution analysis to determine the contributions of different Q^n modes. Table 2 Glass compositions (in equivalent percentages – eq.%) of well characterized glasses

Given glass name/type	Modifiers		Concentration (eq.%)					Reference
	M1	M2	M1	M2	Si	Al	N	
Standard composition M-SiAlON	Mg, Ca, Y, lanthanides		28		56	16	0 – 22	Hampshire <i>et al.</i> (1985)
Mixed modifier standard composition M1-M2-SiAlON	Mg, La or Nd	Y or Er	0 – 28	28 – 0	56	16	17	Pomeroy <i>et al.</i> (2003)
Standard composition Y-, Ln-SiON B-phase	Lanthanides, Y Y, Er, Yb		36 37		64 42	0 21	0 – 20 0 – 22	Ohashi <i>et al.</i> (1995) Menke <i>et al.</i> (2000), Doleckecic <i>et al.</i> (2007)
Wollastonite	La, Nd		42.5		57.5	16	0 – 45	Zhang <i>et al.</i> (1996)
Rare Earth RE-MgSiON	RE = Sc, Y, La, Nd, Sm, Gd, Yb, Lu	Mg	20	20	60	0	0 – 30	Lofaj <i>et al.</i> (2004a,b)
Mixed Ca-M2 SiAlON	Ca	Er, Nd, Y	20 – 10	0 – 10	50	30	0 – 20	García-Bellés <i>et al.</i> (2013), Clausell <i>et al.</i> (2018)

**Fig. 9** Representative structures showing that with N addition, Q³ SiO₄ unit transforms to a Q⁴ unit. SiO₃N units with nominal – 5 charge require extra local positive charge for charge compensation. This allows modifier ions such as Y³⁺ to be accommodated as “network dwelling” cations within the network without creating non-bridging oxygens (NBOs).

The [SiO₃N]^{5–} group requires the presence of an extra positive charge locally to balance the extra negative charge from the N anion and therefore the situation is somewhat similar to that for an [AlO₄]^{5–} tetrahedron within the network, which also requires an extra positive charge to make it isoelectronic with the SiO₄ tetrahedron. However, extra Si cations are introduced into the system by Si₃N₄ and, because each N is coordinated to 3 silicon atoms, therefore, oxynitride glasses containing SiO₃N groups can accommodate more modifiers in charge compensating “network dwelling” sites than the equivalent oxide glasses without creating NBO's as shown in Fig. 9.

Al Bonding and Coordination in M-Si-Al-O-N Glasses (M – Modifier)

In M-Si-Al-O-N glasses, Al, as well as Si, can be in 4-fold coordination with oxygen (and potentially with N) and thus, be a network former (Lemercier *et al.*, 1996; McMillan *et al.*, 1998). However, the Al-O network bond would be somewhat weaker (and less covalent) than the Si-O bond. On the other hand, while Si-N bonding is prevalent in SiAlON glasses, most studies indicate that Al-N bonding does not occur in many oxynitride glasses (Unuma *et al.*, 1992; Sakka, 1995; McMillan *et al.*, 1998). Typically, the Al coordination with oxygen can be 4, 5 or 6 in oxide and non-oxide glasses. For example, Schneider *et al.* (1997) indicated that in their Si-Al-O-N glasses well over half of the Al was coordinated with four oxygens, ~ one third being five-fold coordinated with the rest in six-fold coordination and that the average Al-O coordination increased as either the Al or N content of the glass increased. Lemercier *et al.* (1996) also noted that the Al coordination with oxygen shifted from 4 to 5 and 6-fold as the Al:Si ratio increased in Y-Si-Al-O-N glasses with fixed Y and N contents which was confirmed by ²⁷Al MAS NMR findings. More Al-O-Si linkages would form displacing Si-O-Si units with little change in NBOs or the degree of cross-linking of the network. On the other hand, increased 5- and 6-fold coordination of Al was observed when the Al:Y ratio decreased in glasses with fixed Si and N contents, and the number of NBOs was suggested to increase due to a decrease in Si-O-Al linkages (Rouxel *et al.*, 1990, 2005).

Even though many glasses studied have sufficient modifier cations to charge balance aluminum in four-fold coordination, the fact that Al exists in 5- and 6-fold coordination confirms its intermediate character. Sakka (1995) indicates that about 56% aluminum is in 4-fold coordination in a glass with cation composition: 21Y:48Si:31Al (eq.%) where Y:Al ratio is 0.68 and the

remaining Al is in 5-fold coordination. Rouxel *et al.* (2005) reported that 75%–85% of Al in glasses in the Ca-, Mg-, Ca-Mg-, Ca-Y-, Mg-Y- and Mg-Ca-Y- Si-Al-O-N systems is in 4-fold coordination and the remaining Al in 5-fold coordination but in these glasses M:Al ratio varied from 2.2 to 2.6.

Using ^{29}Si and ^{27}Al MAS NMR, Leonova *et al.* (2008) explored the structures of La-Si-(Al)-O-(N) glasses prepared using the lanthanide metal with a wide range of cation/anion compositions (up to 60 eq.% N). As N content increases SiO_3N tetrahedra dominate in glasses containing <20% N but SiO_2N_2 units are found in glasses with >35% N in La-Si-Al-O-N glasses and requiring >50% N in samples devoid of Al. Al is predominantly present in tetrahedral coordination as AlO_4 units in aluminosilicate glasses and in La-Si-Al-O-N glasses with <20% N. Al in 5-fold coordination amounts to ~10% of the total and < 5% of Al is in octahedral coordination. Whereas there are clear preferences for forming Si–N bonds, Al–N bonding occurs in glasses containing at least 35% N. This corroborates the findings of Deckwerth *et al.* (2001) who detected AlO_3N and AlO_2N_2 tetrahedra by ^{27}Al MAS NMR spectroscopy in contrast to an earlier report by the same authors (Schneider *et al.*, 1997) based on XPS where they found no evidence of Al–N bonding. Thus, in the high N content La-Si-Al-O-N glasses prepared by Leonova *et al.* (2008) SiO_2N_2 and AlO_3N tetrahedra are dominating and interlinked mainly through Si–N–Si and Si–O–Al bridges.

The Role of Modifier (M) Cations

Field strength calculations (Rouxel, 2007) are often used to consider bond strengths within glasses. These are based on Coulombic interactions between a cation and an anion and provide some general insights into the relative strengths of various M–O (or N) bonds. The relationship most frequently used is the cationic field strength:

$$\text{CFS} = z_c / (r_c)^2 \quad (13)$$

where z_c is the ionic charge and r_c the ionic radius of the cation. Generally, network formers have higher CFS values, modifiers have low values and intermediates have intermediate values.

The difference in charge between $[\text{AlO}_4]^{5-}$ and $[\text{SiO}_4]^{4-}$ tetrahedra in the network requires that additional cations are present locally for charge balance (e.g., Mg^{2+} , Ca^{2+} , Y^{3+} , Ln^{3+}). Although the Y–O bond is weaker than the oxygen bond with either Si or Al, its coordination with multiple oxygens and the associated high cationic field strength indicates that Y can improve the strength of the glass network (Becher *et al.*, 2011). In oxynitride glasses, as shown earlier (Hampshire *et al.*, 1985; Videau *et al.*, 1997), the addition of Mg can cause Al to take on more 6-fold coordination with oxygen and go into four-fold coordination with oxygen itself and thus become a network former as nitrogen is incorporated in the glass. In this case, the Si–N bonding introduces extra bridging bonds and cross linkages of Mg–O–Si network chains while Al^{3+} serves for charge compensation. In mixed cation Ca–Mg–Si–Al–O–N glasses Mg has a higher CFS than calcium, which means that the replacement of Ca by Mg increases the rigidity and the stiffness of the vitreous network (Rouxel *et al.*, 2005). In oxynitride glasses, the partial occurrence of Mg in tetrahedral positions, which is enhanced by the presence of nitrogen, leads to an increase of the CFS of Mg atoms so that network compactness is higher than in the corresponding oxide glass. Therefore, effects directly related to the tightening of the network, such as property changes, are expected to increase.

On the other hand, substitution of Ca for Y in Ca–Y–Si–Al–O–N glasses does not appear to alter AlO_4 coordination and so a highly cross-linked network forms (Si–O–Al and Si–N–Si linkages), with randomly distributed Ca^{2+} in network interstitials (Videau *et al.*, 1997; Rouxel *et al.*, 2005).

Rare earth (RE) aluminosilicate glasses contain high field strength trivalent RE^{3+} cations. Based on the ionic radii given by Shannon (1976) and assuming 6-fold coordination of RE^{3+} , field strengths fall in the intermediate range from $2.94 \text{ \AA}^{-2}$ for Ce^{3+} to $4.05 \text{ \AA}^{-2}$ for Lu^{3+} , reflecting the higher cation–oxygen bond energies. Field strength for La^{3+} is $2.82 \text{ \AA}^{-2}$, similar to that for Ce^{3+} , and CFS for Y^{3+} is $3.70 \text{ \AA}^{-2}$. In Y glasses with increasing Y:Si ratio, the ^{29}Si NMR peak shifts upwards, indicating a smaller shielding of the Si nucleus because of the substitution of Y for Al, which may be related to the conversion of BO's to NBO's (Uhlig *et al.*, 1998). At the same time, peaks become narrower, suggesting an ordering of the network. ^{27}Al MAS NMR analysis by Schaller and Stebbins (1998) shows that one major effect of Y^{3+} is to promote the conversion of AlO_4 groups to higher-coordinate species (5 or 6). La acts as a network modifier in La–Si–Al–O–N glasses in that it depolymerizes the Si tetrahedral network with $\text{Q}^n \Rightarrow \text{Q}^{n-1}$ conversions (Leonova *et al.*, 2008). A slight deshielding of the $^{27}\text{Al}_{\text{IV}}$ signals with increasing La^{3+} content is observed which may indicate some depolymerization also of the AlO_4 tetrahedra.

The large ionic radii of the rare earths (RE) and the more ionic character (~70%, based on electronegativity calculations) of the RE–O bond result in higher coordinations with oxygen. i.e., $\text{CN} \geq 6$ (Menke *et al.*, 2000). This also depends on the $r_{\text{RE}}:r_{\text{O}}$ ionic radii ratio where Er and larger REs having 7–9-fold coordination and smaller REs having 6-fold coordination. In oxide and oxynitride glasses with cation compositions of 55Si:20RE:25Al and 45Si:30RE:25Al there is a greater number of Si tetrahedron bridges (i.e., an increased population of higher Q^n values) as the ratio of Si to RE increases. This trend indicates that Si–O–Si bridges are promoted at the expense of Si–NBO–RE linkages when Si replaces RE, resulting in an overall increase in network connectivity. In both the oxide and oxynitride series, the number of Si tetrahedron bridges increases as the size of the RE cation decreases (as CFS of RE increases), thus promoting greater network connectivity.

It can be concluded that, generally, the glass network in oxynitride glasses comprises $\text{SiO}_{(4-x)}\text{N}_x$ tetrahedra, with average x values controlled by N:Si ratios, which are bridged either by Si–O–(Si,Al) linkages or tri-coordinate N–Tetrahedra linkages, and also AlO_4 tetrahedra which are mainly bridged by bi-coordinate O–Tetrahedra linkages.

These structural changes with N substitution for oxygen have significant effects on glass properties which will be reviewed elsewhere.

Introduction

In modern industrial sectors, such as microelectronics, optoelectronics, communications technologies and biomedical devices, research continues to find useful lighter, stiffer materials, including glasses, with superior mechanical properties such as higher elastic moduli, hardness, strength and fracture toughness. The replacement of some of the oxygen atoms by nitrogen in oxide glasses (principally silicates, aluminosilicates and phosphates) leads to definite improvements in these properties and changes in thermal and other properties as a result of extra cross-linking of the glass network when nitrogen substitutes for oxygen.

The preparation, structure and properties of these oxynitride glasses have been extensively studied and some success has been achieved in understanding how changes in glass composition affect structural parameters and their relationship to properties. A number of reviews of oxynitride glasses have been published (Hampshire, 1993; Leng-Ward and Lewis, 1989; Sakka, 1995; Hampshire, 2003, 2008; Pomeroy and Hampshire, 2008a; Becher *et al.*, 2011; see also Hampshire, 2021, this volume).

Initial Studies of Effects of Nitrogen on Properties of Oxynitride Glasses

In the earliest reports of oxynitride glasses (Mulfinger, 1966), it was shown that small concentrations of nitrogen increased the softening temperature, viscosity and crystallization resistance of soda-lime-silica glasses. Elmer and Nordberg (1967) observed significant increases in indentation hardness and electrical resistivity, and a decrease in thermal expansion coefficient when nitrogen was incorporated into a borosilicate glass. A higher annealing temperature was required for these N-containing glasses.

Coon *et al.* (1983) studied the effect of nitrogen on Na-Si-O-N, Na-Ca-Si-O-N and Na-B-Si-O-N glasses and found that Young's modulus (*E*), microhardness and fracture toughness increased with increasing N content. Schrimpf and Frischat (1983) studied Young's modulus (*E*) and viscosity in N₂-containing Na₂O-CaO-SiO₂ glasses, both properties increasing with N content. They calculated Young's modulus for the glass based on mole fractions of component oxides along with considerations of the different ways in which N could be bonded with SiO₄ tetrahedra:

By comparing experimental data and calculated values of *E*, it was concluded that the most prevalent linkages were tri-coordinated N as in (a) above.

Jack (1977) suggested that as little as 1 at% N could increase the softening temperature, viscosity and devitrification resistance of M-Si-Al-O-N glasses (*M* = Mg, Y). Loehman (1979, 1980) prepared M-Si-Al-O-N (*M* = Ca, Mg, La, Y) glasses and proposed that nitrogen content could be correlated with properties. Glass transition temperature (*T_g*), microhardness and fracture toughness were seen to increase while thermal expansion coefficient decreased with increasing amounts of nitrogen added to these aluminosilicate glasses. However, the nitrogen was added as silicon nitride and therefore increases in N content in these glasses would also have resulted in increases in Si:(*M* + Al) ratio and, therefore, the changes in properties would have been influenced by the cation concentrations and were not due only to increases in N content.

Systematic investigations by Drew *et al.* (1981) measured the properties of glasses with fixed M:Si:Al cation ratios and, thus, they were able to show, unambiguously, how changes in N:O ratio affected properties. For glasses in the Ca-, Mg-, Nd- and Y- Si-Al-O-N systems with fixed cation composition of (eq%) 28M: 56Si:16Al, incorporation of nitrogen results in increases in glass transition temperature (*T_g*), shown in Fig. 1, and also microhardness, viscosity, resistance to devitrification, refractive index, dielectric constant and a.c. conductivity (see Hampshire *et al.*, 1985).

Sakka *et al.* (1983) reported increases in glass transition temperature (*T_g*), softening temperature (*T_s*) and microhardness (*H_v*) for Ca-Si-Al-O-N glasses where the mole ratios of the original oxides were kept constant: 36CaO:24Al₂O₃:40SiO₂ and up to 5.5 wt% N was introduced by addition of Si₃N₄ or AlN. They also showed that Young's modulus (*E*) of a Y-Si-Al-O-N glass increased with N content. It was suggested that, in view of increases in density with nitrogen, increases in *H* and *E* were due to compaction of the glass network. Homeny and McGarry (1984) reported increases in density, hardness, Young's modulus and fracture toughness with increasing nitrogen content for a series of Mg-Si-Al-O-N glasses with fixed Mg:Si:Al ratio and up to 4.6 wt% N.

Fig. 1 Effect of N (eq%) on glass transition temperature (T_g) for glasses with fixed cation ratio of 28Y:56Si:16Al. After Hampshire, S., 2008. Oxynitride glasses. *Journal of the European Ceramic Society* 28, 1475–1483.

In a more extensive study of the Y–Si–Al–O–N system (Hampshire *et al.*, 1994), it was confirmed that glass transition temperature (T_g), viscosity, microhardness and elastic moduli all increase systematically while coefficient of thermal expansion (CTE) decreases with increasing N:O ratio for different series of glasses. The same trends were also confirmed by Sun *et al.* (1996) and more extensive data is given by Becher *et al.* (2011). As an example, Fig. 2 shows that values of Young's modulus increase by up to 25%–30% as ~17–20 eq% N is substituted for oxygen at fixed cation ratios (Hampshire *et al.*, 1994; Sun *et al.*, 1996).

It was considered that these effects were due to changes within the glass structure as 2-coordinated bridging oxygen atoms are replaced by 3-coordinated nitrogen atoms which leads to increased cross-linking of the network (Mulfinger, 1966; Hampshire *et al.*, 1985; Hampshire, 2008; see also Hampshire, 2021, this volume).

Structural Considerations in Relation to Properties

Properties are often correlated with a structural parameter, the glass compactness (C_g) which is calculated according to the expression:

$$C_g = (\sum x_i V_i \cdot N) \rho / \sum x_i M_i \quad (1)$$

where x_i is the ionic fraction of ion i , V_i the spherical volume of ion i , and M_i is its ionic mass; N is Avogadro's number and ρ is the glass density. The value for V_i can be calculated using the ionic radii given by Shannon (1969), although this may depend upon their local coordination within the glass. Glass compactness, also known as the atomic packing density, represents the minimum theoretical volume occupied by the ions in the glass divided by the overall effective volume or molar volume (MV) of the glass.

$$MV = \sum x_i M_i / \rho \quad (2)$$

Free volume (FV) is equal to molar volume less the volume occupied by ions. C_g has proven to provide predictions of the major trends in glass properties (Rouxel, 2007). In terms of the increases observed in oxynitride glass properties with increasing nitrogen, N to modifier bonding is more covalent and leads to higher glass compactness (Pomeroy and Hampshire, 2008a; Becher *et al.*, 2011) and rigidification (Richet *et al.*, 2010) of the glass structure.

Field strength calculations (Rouxel, 2007) are often used to consider bond strengths within glasses. These are based on Coulombic interactions between a cation and an anion and provide some general insights into the relative strengths of various M–O (or M–N) bonds. The relationship most frequently used is the cationic field strength:

$$CFS = z_c / (r_c)^2 \quad (3)$$

where z_c is the ionic charge and r_c the ionic radius of the cation. Generally, network formers have higher CFS values, modifiers have low values and intermediates have intermediate values (see also discussion in Hampshire, 2021, this volume).

The strength of the Si–O bond ($U_{\text{Si-O}} = 452$ kJ/mol) is apparently stronger than for the Si–N bond ($U_{\text{Si-N}} = 355$ kJ/mol), which means that Si–O has a greater stretching force constant; however, calculations show that the Si–N bond is more resistant to bending (Rouxel, 2007), which combined with the increased coordination with Si would increase the rigidity of the network. Bonding is much more covalent for Si–N than for Si–O and the bending resistance of the N–Si≡ unit is almost ten times higher than that of the O–Si= unit (De Graaf *et al.*, 2004) so enhancing network rigidity. As a result, bending is more difficult for Si–N–Si than for Si–O–Si linkages, contributing to greater stiffness and increases in elastic modulus (Becher *et al.*, 2011).

Fig. 2 Effect of N (eq%) on Young's modulus (E) for glasses with fixed Y:Si:Al ratios. Data from Hampshire, S., Nestor, E., Flynn, R., *et al.*, 1994. Effect of Nitrogen on Hardness and Young's Modulus

Property data for oxynitride glasses (Sun *et al.*, 1996; Lofaj *et al.*, 2003; Pomeroy *et al.*, 2003; Rouxel *et al.*, 2005; Dölekçekiç *et al.*, 2007) have been analyzed (Pomeroy and Hampshire, 2008a) and most reports show good linear relationships between glass property values and nitrogen content with correlation coefficients generally of the order of 0.99. For microhardness, the gradients lie in the range 0.07–0.13 GPa eq% N^{-1} as shown in Table 1. Generally then, the substitution of 20 eq% N for oxygen in these glasses would be expected to increase the hardness of the glass by 1.4–2.6 GPa. The increased rigidity and degree of network compaction with nitrogen content of oxynitride glasses is often cited for the increase in hardness with nitrogen content (Hampshire *et al.*, 1984; Lofaj *et al.*, 2003; Pomeroy *et al.*, 2003; De Graaf *et al.*, 2004; Rouxel *et al.*, 2005; Daucé *et al.*, 2008; Pomeroy and Hampshire, 2008a; Paraschiv *et al.*, 2015).

Based on data of oxynitride glass hardness for a wide range of glass compositions in the literature, Paraschiv *et al.* (2015) investigated whether the change in hardness due to partial replacement of oxygen by nitrogen in an oxide glass can be quantitatively predicted using only basic topological information about the glassy network. They also presented new hardness data for a series of alkaline earth aluminosilicate glasses containing nitrogen. A model was derived, based on the topological constraint theory (Mauro, 2011), to account for the effect of N for O substitution on glass hardness. Analysis of the wide range of experimental data confirmed that glass hardness increases approximately linearly with the nitrogen content, suggesting its independence of the base oxide cation composition. By deriving the topological bond constraint model of glass hardness and comparing it to the experimental data, it was inferred that this increase in hardness can be quantitatively predicted by a simple enumeration of the additional room temperature bond-stretching and bond-bending constraints arising from the N for O substitution (Paraschiv *et al.*, 2015). The conclusion was that the topological model may thus be useful for designing new oxynitride glass compositions with targeted hardness values.

As shown in Table 2, for elastic modulus, E, gradients of the plots of E v. N content are in the range 0.85–1.8 GPa eq% N^{-1} with the majority of gradients in the range 1.1–1.4 GPa eq% N^{-1} . It is worth noting that the maximum gradient of 1.8 GPa eq% N^{-1} was obtained from data acquired using nanoindentation rather than the ultrasonic pulse echo method by which the other data were measured. Generally then, the substitution of 20 eq% N for oxygen in these glasses would be expected to increase Young's modulus by 22–28 GPa.

Effect of Nitrogen on Thermal Properties

Changes in Viscosity with Nitrogen Content

Rouxel *et al.* (1992) and Hampshire *et al.* (1994) observed that viscosity increases by almost 3 orders of magnitude simply by replacing 17 eq% oxygen by nitrogen in a series of glasses with composition (eq%): 28Y:56Si:16Al:(100 - x)O: xN (x = 0, 10, 17). Fig. 3 shows the viscosity-reciprocal temperature relationships for these glasses derived from 3-point creep tests on the glasses. The presence of nitrogen leads to a significant decrease in creep strain. The transient creep is reduced and a steady-state stage is reached much more quickly (Rouxel *et al.*, 1992). The creep rate dependence on stress during stationary creep was measured from incremental stress steps at a constant temperature of 900°C for the glass containing 10 eq% N. The stress exponent, n, was found to be equal to 1.01, which suggests a linear viscoelastic behavior. Similar trends have been reported for other oxynitride glasses containing different modifying cations and with different cation ratios (Becher and Ferber, 2004).

Variation of T_g with N Content

As with other properties, linear correlations are also observed between nitrogen substitution levels and glass transition temperature as was shown in Fig. 1 with good correlation coefficients. Pomeroy and Hampshire (2008a) analyzed gradients and standard error values obtained from linear regression analysis of data of T_g v. nitrogen content from various reports in the literature (Hampshire *et al.*, 1984; Sun *et al.*, 1996; Pomeroy *et al.*, 2003; Lofaj *et al.*, 2004b; Rouxel *et al.*, 2005; Dölekçekiç *et al.*, 2007). Regression coefficients were close to 0.99 for fourteen sets of data analyzed with standard error values in the range 1.3–7.8°C, indicating excellent linear correspondence between glass transition temperature and nitrogen substitution level. Gradients fall between 2.6 and 4.1°C eq% N^{-1} with most values falling close to 3°C eq% N^{-1} . Accordingly, a general rule can be established that the effect of nitrogen in oxynitride glasses is to increase glass transition temperature by about 3°C for each equivalent percentage nitrogen substituted for oxygen. For a 20 eq% N substitution level, therefore, increases of about 60°C are expected. Littleton softening temperatures (Lofaj *et al.*, 2004b) and

Fig. 4 Effect of nitrogen content on molar volume and fractional glass compactness for a series of glasses with cation composition (eq%): 37Y:42Si:21Al. Data from Dölekçekiç, E., Pomeroy M.J., Hampshire, S., 2004. The effect of preparation route and nitrogen content on Y-SiAlON glasses. Key Engineering Materials 264–268, 1927–1930.

dilatometric softening temperatures, $T_{s,dil}$. (Pomeroy *et al.*, 2003; Dölekçekiç *et al.*, 2004, 2007) also increase linearly with nitrogen content. In general, slopes of plots of $T_{s,dil}$ v. N content are similar to those for T_g v. N, i.e., in the range $2.3\text{--}3.8^\circ\text{C eq\% N}^{-1}$.

Effect of Nitrogen Content on Glass Molar Volume and Fractional Glass Compactness

A number of studies (Pomeroy *et al.*, 2003; Dölekçekiç *et al.*, 2004; Lofaj *et al.*, 2004b) have shown good linear correlations between molar volume and N content and between fractional glass compactness and N content of oxynitride glasses. Fig. 4 shows a plot of molar volume and fractional glass compactness as a function of nitrogen content for a glass with cation composition: 37Y:42Si:21Al (eq%). There are clearly linear correlations. The changes in compactness (atomic packing) indicate that the replacement of oxygen by nitrogen induces a contraction of the glass structure, which is linked to the increased coordination of nitrogen compared to oxygen. Fig. 5 shows data for this glass which exemplifies the linear dependence of Young's modulus, E , on fractional glass compactness and also shows that there is linear correspondence between microhardness, H_v , and glass compactness. Rouxel (2007) has conclusively shown that, for a wide variety of different types of glasses, Young's modulus is controlled by the compactness of the glass structure. Thus, the linear trend shown in Fig. 5 between Young's modulus and fractional glass compactness is wholly expected. Other data for Ca- and Ca-Y-Si-Al-O-N glasses confirm linear relationships between Young's modulus (and hardness) and fractional glass compactness.

Structural Implications of Nitrogen Content – Property Relationships

Based upon the data presented, it is clear that linear relationships arise between the nitrogen content of oxynitride glasses and elastic modulus, hardness, glass transition temperature, dilatometric or Littleton softening temperature, $\log(\text{viscosity})$, molar volume and fractional glass compactness. In addition, the gradients of the linear relationships are similar for a wide range of different oxynitride glass compositions and modifier types. The linearity of the relationships can be explained by the fact that each eq% nitrogen substitution introduces the same number of additional crosslinks into the glass network. Accordingly, the extent of network crosslinking will increase linearly with eq% N. This will have the result of contracting the glass network thus increasing glass compactness and decreasing molar volume in a linear manner. For glass transition temperature (T_g) and the softening temperatures, increased levels of crosslinking will increase resistance to the vibration of atoms (T_g) or the relative movement of glass structural units (softening). Thus, values of T_g and the softening temperatures should also increase linearly as oxygen is sequentially replaced by nitrogen. The same arguments can be made for viscosity since increased crosslinking will increase the resistance to the shear of structural units over one another. Whilst good linear correlations exist between elastic modulus or microhardness and nitrogen content, Rouxel (2007) shows that they are an indirect result of increases in fractional glass compactness and decreases in molar volume. Accordingly, fractional glass compactness and molar volume data are essential to a full understanding of how properties vary with glass composition.

Subcritical Crack Growth (SCG) Resistance of Oxynitride Glasses

The subcritical crack growth (SCG) resistance in water of Y-Si-Al-O-N glasses and their oxide equivalents have been reported using different loading configurations (Coon, 1998; De Graaf *et al.*, 2006a) but with the same relationship between crack velocity,

Fig. 5 Effect of fractional glass compactness on microhardness and Young's modulus for a series of glasses with cation composition (eq%): 37Y:42Si:21Al. 5N, 8N, 17N, 22N refer to nitrogen contents (in eq%). Data from Dölekçekiç, E., Pomeroy M.J., Hampshire, S., 2004. The effect of preparation route and nitrogen content on Y-SiAlON glasses. *Key Engineering Materials* 264–268, 1927–1930.

v , and the applied stress intensity, K_I :

$$V = A(K_I)^n \quad (4)$$

where A is a constant and n is the power-law exponent. De Graaf *et al.* (2006a) found that n for a Y-Si-Al-O-N glass containing ~7 at% N was significantly higher ($n = 63$) than for a yttrium aluminosilicate glass ($n = 21$), while Coon (1998) reported, for a Y-Si-Al-O-N glass containing 18 at% N, subcritical crack velocities in the range 5×10^{-7} – 6×10^{-5} m/s, obtained for stress intensities ranging from 0.675 to 0.686 MPa $m^{0.5}$, respectively, and an even higher value of n ($= 142$).

Variations in Optical Properties with Nitrogen Content

Optical properties of oxynitride glasses have been studied. The refractive index of all oxynitride glasses was found to increase with increasing nitrogen content (Drew *et al.*, 1981; Coon *et al.*, 1989) due to its high ionic polarisability. Near IR transmission of a Ca-Si-Al-O-N glass significantly increases, and the absorption at 2.7 μm observed for the oxide glass disappears when 18 eq% nitrogen substitutes for oxygen, whereas UV transmission was found to be impaired, the absorption edge shifting to longer wavelengths (Drew *et al.*, 1981; Hampshire *et al.*, 1985).

Effects of Cation Composition on Properties of Oxynitride Glasses

Y-Si-Al-O-N Glasses

The effect of varying Si:Al and Y:Al ratios on properties of glasses with constant O:N ratio were investigated by: Hampshire *et al.* (1994); Sun *et al.* (1996); Hampshire and Pomeroy (2004); Becher *et al.* (2011). As Si:Al ratio increases, T_g and viscosity increase while elastic moduli, hardness and thermal expansion coefficient decrease. With increasing Al:Y ratio, elastic moduli and thermal expansion coefficient decrease while the T_g and viscosity decrease to a minimum at 16 eq% Al and then increase with further increase in Al content.

With a fixed N content of 17 eq% and fixed Si content of 56 eq%, as Y:Al ratio decreases, there is a reduction in viscosity of greater than 1 order of magnitude as Al content increases from 4 eq% to 16 eq% Al and then, with further increase in Al to 22 eq%, viscosity increases again. Overall, these effects can be assumed to be related to changes in the density of the glass network and the numbers of non-bridging oxygens as Al changes from 4-fold coordination with oxygen to 5- or 6-fold. At higher Al:Y ratios, when 4 co-ordinated Al is prevalent, enhancement of the cross-linking of the glass network occurs, caused by the formation of more Al-O-Si linkages as Raman spectroscopy analyses indicated (Rouxel *et al.*, 1990). It appears that changes in the Al:Si ratio do not affect the degree of cross linking of the network significantly but simply lead to the replacement of Si-O-Si bridges by Al-O-Si linkages.

Rare Earth (RE) Oxynitride Glasses

Properties of various RE-Si-Al-O-N glasses have been investigated by a number of authors (Murakami and Yamamoto, 1994; Ohashi *et al.*, 1995; Ramesh *et al.*, 1997; Menke *et al.*, 2000a,b; Becher *et al.*, 2002, 2011; Pomeroy *et al.*, 2005). As the atomic number of the lanthanide ion increases, the rare earth ion size decreases and glass transition temperature (T_g), softening temperature (T_s), Young's modulus and hardness increase linearly with increases in cation field strength, CFS (where $CFS = v/r^2$,

Fig. 6 Changes in Young's modulus of RE-Si-Al-O-N glasses as a function of cation field strength and nitrogen contents. Young's modulus increases with increase in N content and with decrease in RE cation radius. Data from Ohashi, M., Nakamura, K., Hirao, K., Kanzaki, S., Hampshire, S., 1995. Formation and properties of Ln-Si-O-N glasses. *Journal of the American Ceramic Society* 78, 71–76. Becher, P.F., Waters, S.B., Westmoreland, C.G., Riester, L., 2002. Influence of composition on the properties of SiREAL oxynitride glasses: RE = La, Nd, Gd, Y, or Lu. *Journal of the American Ceramic Society* 85, 897–902. Becher, P., Hampshire, S., Pomeroy, M.J., *et al.*, 2011. An overview of the structure and properties of silicon-based oxynitride glasses. *International Journal of Applied Glass Science* 2, 63–83.

v = valency, r = ionic radius). **Fig. 6** shows linear changes in Young's modulus as a function of RE cation field strength for glasses with different fixed cation ratios and fixed O:N ratios (data on RE-Si-Al-O-N compositions from [Becher *et al.*, 2002](#); data on RE-Si-O-N compositions from [Ohashi *et al.*, 1995](#); calculation of CFS from ionic radius assuming 6-fold coordination of RE with O). As the rare earth cation field strength increases (decreasing ionic radius), the Young's modulus increases linearly.

However, differences were noted for Eu and other rare earths which did not always fall on the $E v$ CFS linear plot ([Menke *et al.*, 2000a,b](#)). Eu^{3+} is known to reduce to Eu^{2+} in aluminosilicate glasses. [De Graaf *et al.* \(2003\)](#) have also shown that both Sm and Yb can undergo a reduction from the trivalent state in oxides to the divalent state in oxynitride glasses, the degree of conversion depending on melting time. Emission spectra of Sm-containing glasses show the presence of both Sm^{3+} as well as Sm^{2+} , which is also reflected in the data for Young's modulus and density. In the reflection spectra of Yb-containing glasses, a broad absorption band for Yb^{2+} indicates a similar reduction, while a second absorption band suggests the presence of some remnant Yb^{3+} . The other properties of these glasses also confirm a mixed Yb oxidation state. These effects are attributed to the reducing power of chemically incorporated nitrogen in the glass matrix, as clearly demonstrated for Eu-Si-Al-O-N glasses ([Menke *et al.*, 2000b](#)). With a change from Eu^{3+} to Eu^{2+} , the luminescence characteristics change ([De Graaf *et al.*, 2003, 2006b](#)) to give an extended range of emission up to longer wavelengths (500–650 nm) which is ascribed to a combination of energy transfer between the different sites and change of the Eu^{2+} site distribution.

Many studies show that the temperature-dependent viscosity shifts to higher temperatures as the rare earth ion size decreases. **Fig. 7** demonstrates the effects of different rare earth cations (RE = Ce, Sm, Eu, Er and also Y) on viscosity – reciprocal temperature relationships for RE-Si-Al-O-N glasses with fixed cation ratio of 28RE:56Si:16Al ([Hampshire and Pomeroy, 2004](#); [Hampshire, 2008](#)). At any temperature (for example, in the range 825–930°C), viscosity decreases by ~ 3 orders of magnitude in the order: $\text{Er} \geq \text{Y} > \text{Sm} > \text{Ce} > \text{Eu}$. As indicated above, Eu is in the +2 state which is a much larger ion than Eu^{3+} . Viscosity, as with other properties, increases almost linearly with increase in cation field strength of the RE ion.

As shown previously, Al content has a significant effect on viscosity. [Becher and Ferber \(2004\)](#) reported viscosity results for alumina-free La-Si-O-N glasses and showed that the viscosity-temperature plots are shifted by approximately +50°C on the temperature scale compared with La-Si-Al-O-N glasses, which represents more than one order of magnitude increase in viscosity at a fixed temperature. Thus, reducing the alumina content of these oxynitride glasses results in more refractory glasses with higher viscosities. Overall, a change of almost 6 orders of magnitude in viscosity can be achieved by increasing N and modifying the overall RE:Si:Al cation ratio and the type of rare earth ion.

The RE ions strongly affect the molar volume of the glass, with the smaller ions exerting stronger bonding (i.e., higher CFS) on the $(\text{Si,Al})(\text{O,N})_4$ tetrahedra and forming a more compact network. Overall, the trends in properties suggest that there is a tightening of the glass network by (1) extra cross-linking as a result of increasing nitrogen content, and (2) a decrease of the rare earth cation radius.

Fig. 7 Viscosity-reciprocal temperature relationships for a series of glasses with cation ratio (in eq%): 28RE:56Si:16Al (RE = Y, Sm, Ce, Eu, Er) and fixed N content of 17 eq%. After Hampshire, S., 2008. Oxynitride Glasses. *Journal of the European Ceramic Society* 28, 1475–1483.

RE-Si-Mg-O-N glasses

Studies of properties and structure of RE-Si-Mg-O-N glasses (RE = Sc, Y, La, Nd, Sm, Gd, Yb and Lu) have also been undertaken (Lofaj *et al.*, 2004a,b) and show similar trends to those found for RE-Si-Al-O-N glasses. Hardness, elastic modulus, viscosity, thermal expansion coefficient, glass transition temperature and softening temperature increase linearly with increasing cation field strength, CFS, as found for RE-Si-Al-O-N glasses.

In these glasses, nitrogen modifies the glass structure by increasing the content of SiO_3N tetrahedra with extra bridging corners at the expense of SiO_4 units sharing only 2 corners, as found also in Er-Si-Al-O-N glasses (Dölekçekiç *et al.*, 2007). In the RE-Si-Mg-O-N glasses, this depends on the rare earth cation; Lu was found to be more effective in formation of SiO_3N units than La (Lofaj *et al.*, 2004a). Replacing La by Lu results in approximately one order of magnitude increase in viscosity.

Effect of Fluorine on Properties of Oxynitride Glasses

One of the major disadvantages to the use of oxynitride glasses for high stiffness/high hardness applications is the fact that melting at temperatures of the order of 1650–1700°C are required to achieve sufficiently low viscosities for glass pouring. Increased glass viscosities also mean that glass forming or drawing processes must be carried out at higher temperatures than are normal for conventional glasses. However, fluorine can be successfully substituted for oxygen at the same time as nitrogen (Hanifi *et al.*, 2009, 2012; García-Bellés *et al.*, 2013). The network terminating effect of fluorine induces significant reductions in glass melting temperatures, T_g and dilatometric softening temperatures. Interestingly, elastic modulus and hardness are virtually unaffected by fluorine substitution.

The effects of nitrogen and fluorine substitution on properties of a Ca-Si-Al-O-N-F glass are independent and additive rather than synergistic. As a result of these independent and additive effects, nitrogen substitution levels affect glass properties in oxyfluoronitride glasses to similar extents as are observed in oxynitride glasses. Young's modulus and microhardness values for these glasses are controlled by changes in fractional glass compactness which in turn is controlled by the free volume of the glass structure which is dependent on the structural changes resulting from compositionally induced variations of crosslink density.

Fluorine substitution for oxygen in Ca-Si-Al-O-N glasses yields significant decreases in glass transition temperature and glass melting temperature as well as increasing nitrogen solubility to levels much higher than that previously reported for F-free oxynitride glasses. The important effect that N results in increased elastic modulus is not diminished by the addition of fluorine. Thus, it is possible to produce novel oxyfluoronitride glasses with a high elastic modulus but melting and working can be carried out at more conventional glass processing temperatures.

Crystallization of Oxynitride Glasses to Form Glass-Ceramics

As with other silicate glasses, oxynitride glasses may be heat treated at the appropriate temperatures to crystallize as glass-ceramics (Hampshire *et al.*, 1985; Leng-Ward and Lewis, 1989; Besson *et al.*, 1993; Ramesh *et al.*, 1996, 1998; Liddell and Thompson, 1997; Gonon *et al.*, 2000; Menke *et al.*, 2005, 2007). The conventional process to produce a glass-ceramic involves two steps: a lower temperature heat treatment of glasses to induce nucleation, generally just above the glass transition temperature, followed by

Fig. 8 DTA curve showing crystallization events at different temperatures in glass with composition (eq%): 28Y:56Si:16Al:83O:17N. Crystal phases formed include different $\text{Y}_2\text{Si}_2\text{O}_7$ polymorphs and $\text{Si}_2\text{N}_2\text{O}$. After Hampshire, S., Pomeroy, M.J., 2012. Grain boundary glasses in silicon nitride: A review of chemistry, properties and crystallisation. *Journal of the European Ceramic Society* 32, 1925–1932.

heating to a second higher temperature, the so-called crystallization temperature, to allow growth of the pre-formed nuclei. The crystalline phases formed depend on both the composition of the parent glass and the heat-treatment process. The glass-ceramic transformations in a glass of composition (in eq%) 28Y:56Si:16Al:83O:17N have been studied (Ramesh *et al.*, 1998) using both classical and differential thermal analysis techniques and these two methods were found to be in close agreement. Optimum nucleation and crystallization temperatures were determined in relation to the glass transition temperature. The major crystalline phases present are mixtures of different forms of yttrium disilicate and silicon oxynitride.

The devitrification of this Y–Si–Al–O–N glass is highly complex due to the fact that all 5 polymorphs of yttrium disilicate can form under varying conditions of heat treatment and also silicon oxynitride as shown in Fig. 8. The optimum nucleation conditions correspond to those which offer the best heterogeneous nucleation condition for the γ - to α - plus β - yttrium disilicate phase transformation. The devitrification processes in Y–Si–Al–O–N glasses can be simplified by partially substituting Y with a rare earth ion such that the average ionic radius of the mixed modifier system is compatible with a single disilicate polymorph (Pomeroy and Hampshire, 2008b; Hampshire and Pomeroy, 2012).

Other crystalline phases which have received some attention include B-phase ($\text{Y}_2\text{SiAlO}_5\text{N}$) (Gonon *et al.*, 2000), Iw-phase ($\text{Y}_2\text{Si}_3\text{Al}(\text{O},\text{N})^{10}$) (i.e., ~ 10 eq% N) and wollastonite (YSiO_2N) which are formed on heat treatment at temperatures below 1200°C of a glass of composition (in eq%) 35Y:45Si:20Al:77O:23N. At higher temperatures heat treatment results in formation of α -yttrium di-silicate ($\text{Y}_2\text{Si}_2\text{O}_7$), apatite ($\text{Y}_2\text{Si}_3\text{O}_{12}\text{N}$) and YAG ($\text{Y}_3\text{Al}_2\text{O}_{12}$) (Hampshire *et al.*, 1994). At relatively low heat treatment temperatures of ~ 950 – 1100°C , the nucleation and growth of N-wollastonite (YSiO_2N) and the intermediate phases B and Iw are kinetically favored over that of the more stable equilibrium phases YAG and $\text{Si}_2\text{N}_2\text{O}$. B-phase has the pseudo α -wollastonite structure. Normally, it might be expected that this structure would consist of layers of Y^{3+} and rings of $(\text{Si},\text{Al})(\text{O},\text{N})_4$ tetrahedra but it was shown that the formation of these rings is suppressed by the incorporation of nitrogen (Gonon *et al.*, 2000).

Further studies, by analytical transmission electron microscopy, including electron spectroscopic imaging, have shown that B-phase forms after crystallization heat treatment at 1050 and 1150°C of Er- and Y/Yb- Si–Al–O–N glasses (Menke *et al.*, 2005, 2007). The crystals take up a wide range of composition; the erbium cation percentage varies around that of the expected B-phase composition ($\text{Er}_2\text{SiAlO}_5\text{N}$), but aluminum content is slightly lower and silicon content higher than this. In addition, Er content is strongly anti-correlated with Si content. A comparison of B-phase compositions after crystallization of equivalent glasses formed with either yttrium, erbium or ytterbium shows that the B-phase solid solution range depends on the particular cation radius. As a consequence of this, the degree of crystallization and the composition of the residual glass will, for equivalent glasses, also depend on the cation radius. In addition to crystal growth, the crystallization heat treatment results in a phase separation of the residual glass whereby smaller Si- and N-rich amorphous features form. These features are effectively pinning the boundaries of growing crystals.

The properties of the glass-ceramics are significantly higher than those of the parent glasses with, for example, values of elastic modulus greater than 200 GPa.

Potential Applications for Oxynitride Glasses

So far, oxynitride glasses have not found any real application. Their potential applications include use as passive coatings on electronic substrates, high-speed hard disk drive substrates. Bachar *et al.* (2016) have studied bioactive glasses containing nitrogen and there may be possibilities of developing bioglasses with improved strength and elastic modulus. Luo *et al.* (2013) investigated

transparent oxynitride glasses with a view to improved ballistic resistance for transparent armor materials. The work of De Graaf *et al.* (2003) shows potential for oxynitride glasses as host materials for LED phosphors. One area of oxynitride glass research that has not been covered here is phosphorus oxynitride glasses based on Li-P-O-N and related systems. These materials may have potential for use in solid-state lithium batteries.

Summary

Oxynitride glass formation occurs in a number of M-Si-O-N, M-Si-Al-O-N and M-Si-Mg-O-N systems. As nitrogen content increases, properties such as glass transition temperature, elastic modulus, viscosity, hardness and slow crack growth resistance increase as a result of increased cross-linking of nitrogen within the glass network. Most reports show good linear relationships between glass property values and nitrogen content with correlation coefficients generally of the order of 0.99. The linearity of the relationships can be explained by the fact that each eq% nitrogen substitution introduces the same number of additional crosslinks into the glass network with the consequent increases in rigidity and degree of network compaction (decrease in molar volume). There is a clear linear dependence of Young's modulus, and also microhardness, on fractional glass compactness.

For a constant cation composition, viscosity increases by more than 2 orders of magnitude as ~ 17 eq% oxygen is replaced by nitrogen. For rare earth oxynitride glasses with constant nitrogen content, viscosity, Young's modulus and Tg and other properties increase linearly with increasing cation field strength (decreasing ionic radius).

Many studies on crystallization of oxynitride glasses have been carried out which have identified suitable two stage heat treatments for nucleation and growth of crystal phases, including different yttrium disilicate phases and B-phase (M_2SiAlO_5N ; M=Y, Er, Y+Yb), to form glass ceramics with significant increases in strength and elastic modulus over the parent glasses.

Addition of fluorine extends glass formation in oxynitride systems and allows dissolution of higher levels of nitrogen into glasses. Fluorine lowers glass transition temperature but does not have any effect on elastic modulus or microhardness.

Phosphate Glasses and Their Use

A study of phosphate glasses was initiated more than 100 years ago by the investigations of Otto Schott *et al.* on the optical properties of alkaline earth phosphate glasses (Kreidl and Weyl, 1941). However, the troubles related to the melting of phosphate glasses and poor chemical durability of these early prepared glasses delayed temporarily their further investigation. In the early 1960s, a noticeable interest in their application as laser hosts reestablished phosphate glass research. One of the advantages of the phosphate glasses is the possibility to dissolve a large amount of rare-earth elements. They also have large rare-earth stimulated emission cross-sections and low nonlinear refractive indices which makes them good material for high power laser radiation (Weber, 1990; Campbell and Suratwala, 2000).

Due to their unique properties such as low melting temperatures and a very high coefficient of thermal expansion compared with silicate-based glasses, the phosphate glasses were thus proven to be good candidates for a variety of specialty applications (Shelby, 2005). In particular, the low glass transition temperature of phosphate glasses, usually in the range 300–400°C, can drop even lower in some specific cases. Furthermore, a thermal expansion coefficient greater than $20 \times 10^{-6} \text{K}^{-1}$ makes phosphate glasses applicable for sealing of low-temperature components, e.g., tin- and zinc-bearing phosphates (Morena, 2000). Along with low processing temperature, <400°C, the most important requirements for the sealing glass formulations are high chemical durability and high electrical resistivity. Therefore, in the permanent search for new sealing glasses, the phosphate-based formulations containing oxynitrides satisfactorily fulfill these conditions, exhibiting an enormous enhancement in the chemical durability (Rajaram and Day, 1988).

Also, the addition of one or more oxides such as Al_2O_3 , CaO , and Fe_2O_3 (Legeros and Lee, 2004) improves significantly the chemical durability. For example, the binary iron phosphate glasses are best known for their exceptional chemical durability and high solubility of various nuclear waste compounds which sets the direction of their application as a host material for vitrification of nuclear wastes (Day *et al.*, 1998; Mesko *et al.*, 1998; Fang *et al.*, 2001). In addition, many studies of phosphate-based glasses are related to electrical conductivity investigations. Lithium phosphate glasses have gained recent interest due to their potential applications as amorphous electrolytes in solid-state batteries (Moreau *et al.*, 2009; Ducdot and Souquet, 2001; Ishiyama *et al.*, 2014; Ravaine, 1980). The liquid lithium electrolytes consist of lithium salts and organic polymer liquids. In contrast, the inorganic solid electrolytes such as phosphate glass-based lithium electrolytes show numerous advantages over the organic liquid solvents (Ducdot and Souquet, 2001). In parallel, accelerating interest in lithium phosphate glass-ceramics made it possible to interpret trends in ionic conductivity and its dependence on the microstructure. A large body of the work on the structural and electrical properties of lithium phosphate compositions, which includes phosphates with NASICON-type (superionic conductors) structures, reveals a structural versatility and wide range of compositions (Fu, 1997; Kotobuki and Koishi, 2013; Patil *et al.*, 2013; Nikolić *et al.*, 2013; He *et al.*, 2014; Nuernberg and Rodrigues, 2017; Nuernberg *et al.*, 2017, 2018; Xiao *et al.*, 2019; Narváez-Semanate and Rodrigues, 2010). The base chemical formula of these compounds can be written as $\text{LiM}_2(\text{PO}_4)_3$, where M is a tetravalent cation such as Ge, Ti, Zr, Sn. Among the aforementioned tetravalent cations, Ti in the $\text{LiTi}_2(\text{PO}_4)_3$ (LTP) system leads to the basic NASICON compound with the highest lithium conductivity and lowest activation energy (Takada, 2013; Cao *et al.*, 2014).

Phosphate glasses containing transition metal oxides (TMO) such as Fe_2O_3 , V_2O_5 , WO_3 and MoO_3 , have been widely investigated in the last few years due to their semiconducting nature that opened another field of applications: in electrochemical, electronic, and optoelectronic devices. It is well known that in these glasses electronic conduction occurs by electron transfer between transition metal ions in different valence states following the small polaron hopping mechanism (Ishiyama *et al.*, 2014; Austin and Mott, 1969; Mackenzie and Nasu, 1985; Murawski *et al.*, 1979; Moguš-Milanković *et al.*, 1999; Nikolić *et al.*, 2018; Pavić *et al.*, 2018a,b). Moreover, phosphate glasses containing alkali and silver oxides in combination with transition metal oxides represent the mixed ion-polaron conductive glasses (Nikolić *et al.*, 2018; Pavić *et al.*, 2018b). In these glass systems, two types of charge carriers, ions and polarons participate in the conduction process making these glasses prospective mixed conductors in solid-state batteries as cathode/anode materials (Nakata *et al.*, 2016). Also, mixed ion-polaron phosphate glass-ceramics have become a subject of numerous studies since many functional glass-ceramics improve mechanical, electrical, magnetic, and optical properties as a result of the controlled glass crystallization (Garbarczyk *et al.*, 2004, 2007, 2009, 2015; Pietrzak *et al.*, 2009, 2011, 2013, 2016a,b; Pavić *et al.*, 2014, 2018a, 2019, 2020; Moguš-Milanković *et al.*, 2012, 2015; Chen *et al.*, 2018).

Phosphate-based glasses and glass-ceramics are the most prominent materials in the repair and regeneration of damaged soft and hard tissues (Jones and Clare, 2012; Ren *et al.*, 2013). The main reason why phosphate glasses are of interest for use as biomaterials is their ability to dissolve completely in aqueous solutions into safe non-toxic dissolution products (biocompatibility). A characteristic of bioactive glasses and glass-ceramics is the formation of a biologically active apatite layer which provides the bonding with bone (Knowles, 2003; Ahmed *et al.*, 2004b). It is worth noting that the bioactivity of glasses mainly depends on the compositions of bioactive materials which can be controlled by the surface modifications, implying various forms of bioactive glass, such as beads or fibers (Hossain *et al.*, 2014). They have also attracted much interest in bone tissue engineering (Rahaman *et al.*, 2011) as well as soft tissue regeneration (Shah *et al.*, 2005) and drug delivery applications (Moioli *et al.*, 2007).

Fig. 1 A three-dimensional network of PO_4 tetrahedra with (a) bridging, (b) non-bridging oxygens and (c) double-bonded oxygens to form the network of vitreous P_2O_5 .

Various properties of phosphate glasses that make them a candidate for numerous applications in many fields are closely related to their atomic structure. In the next section, a brief review is given of the main structural features of phosphate glasses with a special emphasis on the bonding arrangements in the glass structures.

Basic Structure of Phosphate Glasses

The electronic configuration of phosphorus (P) is $3s^2 3p^3$ that forms four sp^3 hybrid orbitals and the fifth electron in d orbital assists in the formation of π -bonding molecular orbitals with 2p oxygen electrons (Cruickshank, 1961; Mitchell, 1969). Consequently, in glasses and crystalline phosphates, the phosphorus creates P-tetrahedra that are connected through the covalent bridging oxygens and form various phosphate anions. Thus, when bonded to oxygens, phosphorus forms several oxide structures but the crucial one is P_4O_{10} (phosphorus pentoxide) where the three P-tetrahedra are bonded through P-O-P oxygens and the fourth is double-bonded to oxygen, $\text{P}=\text{O}$. Fig. 1 shows a three-dimensional network of PO_4 tetrahedra with bridging oxygens (a), non-bridging oxygens (b) and double-bonded oxygen (c). Phosphorus (P) having tetrahedral coordination is classified as a network former element and Zachariasen (1932) identified a vitreous P_2O_5 as a typical distorted network glass former oxide.

The phosphate glass network is constructed of PO_4 units interconnected through bridging oxygens, where at least one of the oxygens is nonbridging (Zachariasen, 1932). The structure of phosphate glasses is usually described by Q^n terminology (Liebau, 1981) where the “ n ” represents the number of bridging oxygens per P-tetrahedron as displayed in Fig. 2. Thus, the Q^3 tetrahedra represent a cross-linked network as in vitreous P_2O_5 , Q^2 corresponds to the polymer-like metaphosphate chains whereas Q^1 is related to the pyrophosphate (dimer) units and Q^0 is associated with isolated orthophosphate anions. Therefore, the structure of phosphate glasses is constituted by various arrangements of phosphate units that depend on the modifier type and concentration. In fact, the modifier oxide addition to the phosphate network causes a break up of P-O-P bonds (depolymerization of the phosphate network) and forms negatively charged P-O⁻ bonds which are compensated with the modifier cations by forming covalent bonds. Moreover, Hoppe (1996) developed a set of rules for network changes upon the addition of modifying atoms to describe the disruption of P-O-P bonding units as a function of P_2O_5 content.

The structure of phosphate glasses depends also on O/P ratio which determines the number of bonds formed through bridging oxygens as depicted in Fig. 2(b). Thilo (1959) classified phosphate compositions into ultraphosphates, ($\text{O}/\text{P} < 3$); polyphosphates ($\text{O}/\text{P} > 3$) and metaphosphates with $\text{O}/\text{P} = 3$. In that sense, Van Wazer (1958) established a description of the local arrangement of phosphate glass polyhedra which depends on the ratio between polymerization/depolymerization degree of phosphate and modifier units. Therefore, the short-range order of phosphate structure is related to the close coordination environment of an ion whereas the medium-range order is defined as linkages of phosphate polyhedra that form larger structures.

In order to clarify the structure of phosphate glasses, there have been two excellent publications (Abe, 1983; Martin, 1991a) and perhaps the most complete and cited review entitled: “Review: the structure of simple phosphate glasses” by Brow (2000) where the most important factors that affect the phosphate glass structure and experimental techniques used are described in detail. Also, a Handbook of Glasses recently published, represents a comprehensive overview of the diverse field of glass science, with an article dedicated to the phosphate glass families providing basic information on their specific applications (Musgraves et al., 2019).

Fig. 2 (a) Phosphate tetrahedra are described by Q^n nomenclature in phosphate glasses. (b) Structural units in phosphate glass network, and (c) O/P ratio for different Q^n structure.

Vitreous P₂O₅ (v-P₂O₅)

Studies of the vitreous P₂O₅ structure analyzed by new structural probes such as solid-state nuclear magnetic resonance (NMR) spectroscopy, X-ray absorption spectroscopy (XAS); and neutron diffraction analyses have been reported (Galeener and Mikkelsen, 1979; Meyer, 1997; Hoppe *et al.*, 1998; Suzuya *et al.*, 1998; Hudgens and Martin, 1993). Since v-P₂O₅ is highly hygroscopic and volatile the preparation of anhydrous glass demands a specific handling procedure, usually in a dry-box (Hudgens and Martin, 1993). Without going into the details of the results of the local structure of v-P₂O₅ from each of these structural probes, it should be pointed out that the basic constituent of P₂O₅ glass is the Q³ tetrahedron having three bridging oxygen bonds to neighboring tetrahedra (*p*-BO) and one short bond to a terminal oxygen (*p*-TO). These tetrahedra are interconnected forming a three-dimensional phosphate network.

Binary and Ultraphosphate Glasses

The introduction of a modifier oxide to v-P₂O₅ creates the non-bridging oxygens, P-NBO, generating depolymerization of the phosphate network where the terminal oxygens are linked to modifier cations and the Q³ tetrahedra are transformed into Q² units. Further addition of modifier oxide significantly depolymerizes the phosphate structure, converting Q² to isolated Q¹ units. Therefore, depolymerization of the phosphate network with the addition of the modifier oxide (R₂O) can be described by the reaction: $2Q^n + R_2O = 2Q^{(n-1)}$ and the glass composition is determined as $(xR_2O)(1-x)P_2O_5$. Depending on R₂O content (x) it is possible to distinguish different types of phosphate glasses. For example, compositions in the range $0 \leq x < 0.5$ represents ultraphosphates which contain some Q² and mainly Q³ phosphate units which are responsible for a high reactivity in water. Metaphosphate network, $x = 0.5$, consists of Q² units and is described as long polyphosphate chains or rings where more modifier ions are bonded to the non-bridging oxygens. In polyphosphate glasses, $x > 0.5$, phosphate chains are shorter and in pyrophosphates, the network is dominated by Q¹ dimer phosphate units with a stoichiometry of $x = 0.67$.

Glass formation of binary phosphate systems containing alkali (R₂O) or alkaline earth (RO) oxides is in the range $x = 0.55$ – 0.65 for the conventional melting process forming glass networks based on Q² units. On the other hand, phosphate glasses with low coordination metal (CN < 6) oxides such as ZnO, PbO, SnO or Fe₂O₃ prepared by a melt quenching process create a structure that mostly consists of pyrophosphate, Q¹, units and molecular segments in which non-bridging oxygens are linked to the smaller valence cations, forming, for example, P–O–Fe²⁺ bonds. Usually, in these glass systems, a small amount of metaphosphate (PO₃)⁻ and orthophosphate (PO₄)³⁻ units co-exist with pyrophosphates units (Fang *et al.*, 2001).

In order to provide a qualitative description of the phosphate glass structure, the most used techniques are Raman and FTIR spectroscopies. Both spectroscopies exhibit characteristic vibrational modes of the different phosphorus units which depend on the depolymerization degree of the phosphate network. Changes in the Raman and FTIR spectra reveal a transition of phosphate structure between the cross-linked network of ultraphosphates and polymer-like long phosphate chains of metaphosphates as a function of type and content of modifier atoms, i.e., variation of the glass composition (Brow, 2000; Musgraves *et al.*, 2019).

New spectroscopic techniques such as ³¹P magic angle spinning nuclear magnetic resonance (MAS NMR) spectroscopy allow quantification of various phosphorous units in the network and determination of the structural environment of phosphorous atoms depending on the degree of polymerization. The chemical shift of the ³¹P nuclei is sensitive to the type of modifier cations that are bonded to nonbridging oxygens which define the bond strength between them. Two-dimensional (2D) ³¹P NMR spectra are employed for detecting the connectivity between phosphorus units through dipolar correlation techniques, such as double quantum (DQ) MAS NMR. In this technique the dipolar interactions between ³¹P nuclei are related to the homo- and heteronuclear (³¹P in combination with other nuclei such as ²⁷Al, ¹¹B, ⁷³Ge, ⁷Li, ²³Na) correlations and hence in 2D plots the proximity between different, for example, Q² and Q¹ sites can be detected. Furthermore, many advanced 2D multiple quantum or pulse sequences NMR techniques can provide additional information on the network bonding connectivity such as INADEQUATE, REDOR, DQ-DRENAR, HECTOR, etc., which are described by Brow (2000) and Musgraves *et al.* (2019). There are also several new probes used in studying the phosphate glass structure such as X-ray absorption spectroscopy (XAS) X-ray photoelectron (XPS)

spectroscopy, and neutron diffraction techniques which provide essential information on bonding arrangements in the phosphate network. Moreover, computational modeling based on *ab initio* (Uchino and Ogata, 1995) and molecular dynamics (MD) (Alder and Wainwright, 1959; Cormack and Cao, 1996) gives rise to knowledge of molecular orbitals interpretation that can explain the influence of the modifying cations on phosphate network changes.

Phosphate Glasses in Biomedicine

Phosphate-based glasses belong to a class of materials with a wide application in diverse fields of biomaterials engineering; from hard and soft tissue repair and regeneration (Knowles, 2003; Kiani *et al.*, 2012; Sharmin and Rudd, 2017; Combes and Rey, 2010) to drug delivery (Baino *et al.*, 2016; Lapa *et al.*, 2020) and dental materials (Combes and Rey, 2010). The versatile nature of phosphate glasses in biomedical applications is based on the fact that they dissolve harmlessly in the body over a timescale that can vary from a few hours to several months depending on their composition (Knowles, 2003; Kiani *et al.*, 2012). Since phosphate-based glasses can incorporate various chemical elements in broad percentages, and can readily be prepared in various geometric forms (disks, microtubes, microspheres, fibers), their solubility can be easily tuned by precise variations in composition and morphology enabling a controlled interaction of the glass and the tissue, and delivery of therapeutically useful substances to the specific target sites at a controlled rate.

A revolutionary step in the medical application of glasses was the discovery of the first bioactive glass by Larry Hench and co-workers in the early 1970s (Hench *et al.*, 1971). They showed that silicate-based glass of composition $45\text{SiO}_2\text{-}24.5\text{Na}_2\text{O-}24.5\text{CaO-}6\text{P}_2\text{O}_5$ (in wt%), known as 45S5 bioglass, provokes positive reactions of tissue resulting in the formation of a biologically active hydroxycarbonate apatite (HCA) layer which provides the bonding interface with the tissues (Hench *et al.*, 1971; Hench, 1998). Therefore, bioactivity can be defined as a capacity of a material to react with physiological fluids and form tenacious bonds to hard and soft tissues through cellular activity (Hench, 1998; Day and Boccaccini, 2005). Over the years, bioactive properties were found in other silicate-based, but also in phosphate-based and borate-based glasses (Islam *et al.*, 2017).

Bioactive phosphate glasses are mainly based on the ternary $\text{Na}_2\text{O-CaO-P}_2\text{O}_5$ system (Knowles, 2003; Islam *et al.*, 2017; Ahmed *et al.*, 2004a,b) which contains elements present in the human body with important biological roles (P, Ca, Na = 1, 1.5 and 0.2 wt%, respectively) (Lapa *et al.*, 2020). However, other modifying oxides such as TiO_2 , SrO, CuO, ZnO, Ag_2O , MgO, and Fe_2O_3 can be added to phosphate glasses to induce specific property, functional, or biological response (Islam *et al.*, 2017). The addition of metal oxides generally increases chemical durability, decreases the tendency for crystallization, and improves the mechanical properties of phosphate glasses, but simultaneously, metal ions can also have an active role in a biological response. For instance, silver and copper ions are known to exhibit antibacterial properties (Knowles, 2003; Lapa *et al.*, 2020), iron ions improve cell attachment (Lapa *et al.*, 2020) whereas calcium, magnesium and strontium ions improve bone mineralization, osteoblast proliferation, and differentiation (Lapa *et al.*, 2020). Altogether, the combination of these properties offers a vast range of possibilities for the development of bioactive phosphate-based glasses for specific biomedical applications such as bone regeneration and bone-ligament regeneration, wound healing, muscle cell delivery systems, and nerve tissue regeneration (Lapa *et al.*, 2020).

Besides the above-mentioned metal ions, many other therapeutic substances have been used or proposed for use with phosphate-based bioactive glasses. These include fluorine which helps prevent dental caries (Knowles, 2003), chemotherapy drug cisplatin (Pickup *et al.*, 2012) and radionuclei for radiotherapy (Sene *et al.*, 2008). For such diverse biomedical applications, the most important requirement is the possibility to prepare glass in various geometrical forms and over a wide range of sizes. Indeed, bioactive phosphate-based glasses have been fabricated in different forms, from disks, microspheres (Ahmed *et al.*, 2019; Hossain *et al.*, 2015; Gupta *et al.*, 2018) to fibers (Sharmin and Rudd, 2017; Lapa *et al.*, 2020) and microtubes (Abou Neel *et al.*, 2007). The phosphate-based glass fibers can be used for cell transportation and device expansion, as a nerve conduit, and as a scaffold for muscle regeneration since they provide tissue-like fibrous constructs that can guide the cell growth (Deshmukh *et al.*, 2020). Also, phosphate glass fibers readily form microtubes and hence can be integrated with various polymers to help nutrient diffusion and ingrowth of vascularization when employed as scaffolds for hard and soft tissue regeneration (Deshmukh *et al.*, 2020). On the other hand, microspheres provide a stable surface for proliferation and cell attachment preventing tissue damage and hemorrhage which make them applicable in radiotherapy (Ahmed *et al.*, 2019; Hossain *et al.*, 2015; Gupta *et al.*, 2018; Deshmukh *et al.*, 2020). The synthesis of bioactive phosphate-based glasses in different forms involves special preparation techniques. The classical melt-quenching produces phosphate-based glass in a bulk form whereas microspheres are commonly manufactured via dropping crushed glass particles down a vertical tube furnace, pouring molten glass onto stainless steel plates to create droplets, sol-gel method and spray drying of sols, and flame spheroidization processes (Gupta *et al.*, 2018). The fabrication of continuous glass fibers has more commonly been achieved via melt drawing but they have also been produced from preformed rods (Ahmed *et al.*, 2019).

Electrical and Optical Properties of Phosphate Glasses

Electrically conducting phosphate glasses have attracted much attention over the last decades due to their potential use either as the electrolyte, electrode material, or other specific components in various modern devices from solid-state batteries and fuel cells, to smart windows and chemical sensors (Dudot and Souquet, 2001; Minami *et al.*, 2006; Cao *et al.*, 2014; Xiao *et al.*, 2019; Grady *et al.*, 2020). In particular, phosphate glasses offer extreme compositional and preparation variability which enables tuning of the

types and mechanisms of the electrical conduction. That is, the type of conduction – ionic, electronic, or mixed polaronic-ionic – depends primarily on the composition whereas the mobility of charge carriers (ions and/or electrons) depends on their interaction with the glass network and local structural setting.

From the point of view of optical and optoelectronic applications, phosphate-based glasses are in high demand since they have been demonstrated to be promising contenders to silicate-based glasses. Thanks to a very open and disordered matrix structure (Seneschal *et al.*, 2005) a high level of rare earth-ions can be incorporated into the phosphate network, hence serving as an excellent host matrix for lasers, fibers, and optical lenses (Yamanaka *et al.*, 1981; Weber, 1990; Ehrt and Seeber, 1991; Hutchinson and Allik, 1992; Jiang *et al.*, 2000). Furthermore, phosphate glasses show the ability to be melted with fluorides for the production of fluoride phosphate/fluorophosphate glasses with excellent optical properties (Möncke and Eckert, 2019) whereas Ag-doped phosphate glass is a well-known radiophotoluminescence (RPL) dosimeter (Piesch and Burgkhardt, 1994; Miyamoto *et al.*, 2011; Kodaira *et al.*, 2018; Sholom and McKeever, 2020). The next sections cover the basics of electrical conduction mechanisms with an overview of important compositional-structural effects on electrical transport and a brief description of the opto(electronic) applications of phosphate glasses.

Ionic and Electronic (Polaronic) Conductivity in Phosphate-Based Glasses

Phosphate glasses containing alkali, alkaline-earth oxides or silver oxides are ionically conducting materials. In these glasses, ionic transport arises from the movement of modifier cations through the glass network (Martin, 1991b; Dyre *et al.*, 2009). Therefore, the ionic conductivity depends on the concentration and the mobility of mobile cations, whereas the mobility itself is influenced by their attractive interactions with the “immobile” glass network, and also by the mutual repulsion interactions between mobile ions themselves.

Depending on the composition, the ionic conductivity of phosphate-based glasses spans many orders of magnitude reaching values comparable to that of liquid electrolytes. For instance, silver phosphate glasses doped with silver halides or silver chalcogenides (Minami, 1987; Rousselot *et al.*, 1995; Bhattacharya and Ghosh, 2004; Bhattacharya *et al.*, 2006; Das *et al.*, 2005; Ren and Eckert, 2013) exhibit extremely high mobility of silver ions and are classified as fast ionic conductors with applications as solid electrolytes in optical switches and memory devices. The fast transport of silver ions in these glasses results from the highly depolymerized phosphate structure lacking typical network connectivity through which silver ions easily diffuse.

Another good example of the role of the glass structure on the dynamics of mobile ions is the phenomenon called the Mixed Glass-Former Effect (MGFE) (Zielniok *et al.*, 2007; Agarwal *et al.*, 2004; Muñoz *et al.*, 2009; Kumar and Rao, 2004; Prasad *et al.*, 1990). The mixed glass-former effect is evidenced in a nonlinear change in ionic conductivity when one glass former is gradually substituted by the second one while the alkali concentration is kept constant. The magnitude of the conductivity increase differs for different glass systems indicating that the origin of this phenomenon is related to the variations in structural arrangements of the network units. This has opened a new research field directed towards the development of lithium ion-based phosphate glass systems suitable for application as electrolytes for lithium batteries (Duclot and Souquet, 2001; Ritchie, 2004). For instance, several reports (Magistris *et al.*, 1985; Muñoz *et al.*, 2009; Raguene *et al.*, 2011; Storek *et al.*, 2012; Larink *et al.*, 2012) have shown that the mobility of Li^+ ions is significantly enhanced when B_2O_3 is gradually substituted by P_2O_5 . Interesting results have been observed on mixed matrix glasses of the type $\text{Li}_2\text{O}-\text{P}_2\text{O}_5-\text{GeO}_2$ and $\text{Li}_2\text{O}-\text{B}_2\text{O}_3-\text{P}_2\text{O}_5-\text{GeO}_2$ containing a fixed amount of Li_2O along with two and three glass-formers, respectively (Sklepić *et al.*, 2017; Moguš-Milanković *et al.*, 2013, 2016; Mošner *et al.*, 2013). Similarly as with B_2O_3 , the addition of GeO_2 has a direct impact on the changes of conductivity through the formation of mixed structural units which serve as compensating sites for lithium ions. Furthermore, it was also reported that the mixing of P_2O_5 and B_2O_3 as glass-forming oxides exhibits a similar effect on Na^+ ion transport due to the formation of bridging B-O-P bonds which enhances easier sodium ion hopping as a result of smaller binding energy for ions (Christensen *et al.*, 2013). This result is promising since it promotes sodium-conducting mixed former systems based on P_2O_5 as an attractive candidate for the new-generation of energy-storage devices containing sodium instead of lithium ions, being almost equally effective in batteries but significantly cheaper.

On the other hand, phosphate glasses containing transition metal oxides (TMOs) such as V_2O_5 , WO_3 , MoO_3 , Fe_2O_3 , are amorphous semiconductors and exhibit electronic conduction via “small polaron hopping” mechanism (Mott, 1968; Mott, 1969; Austin and Mott, 1969; Murawski *et al.*, 1979; Šantić and Moguš-Milanković, 2012). In these glasses, the TM ions are present in different oxidation states and the conduction takes place by thermally activated small polaron hopping from the TM ion of lower to TM ion of higher oxidation state. Therefore, polaronic transport depends on the total amount of TMO as well as on the relative fraction of TM ions in different oxidation states (Moguš-Milanković and Day, 1993; Moguš-Milanković *et al.*, 2004, 2005a,b, 2012; Šantić and Moguš-Milanković, 2012; Nikolić *et al.*, 2018). While the amount of TMO is a matter of choice of the glass stoichiometry and can vary widely in phosphate glass, the fraction of TM ions in different oxidation states is determined by the equilibrium between TM redox couples in the melt:

The above redox reaction depends upon several factors such as melting temperature, time, atmosphere, types of raw materials, and the presence of other substances in the batch (Moguš-Milanković and Day, 1993; Ray *et al.*, 1999; Fang *et al.*, 2001). By varying these factors, the fraction of TM ions in the glass changes which directly influences the polaronic conductivity. Interestingly,

however, polaronic conductivity in phosphate glasses containing Fe_2O_3 and MoO_3 depends strongly on the fraction of TM ions in different oxidation states, whereas for phosphate glasses with V_2O_5 and WO_3 polaronic conductivity is more influenced by the features of the glass structure, in particular clustering of transition metal units which facilitates the transport of polarons. The application of polaronic phosphate glasses includes the development of electrode materials and is directed towards designing more complex mixed polaron-ion conductive glasses.

Mixed Polaron-Ion Phosphate Glasses

Interest in investigating mixed conductive phosphate glasses is the fact that TMOs along with alkali oxides as modifiers can form glasses with P_2O_5 glass-former in a wide compositional range. Based on this, these glasses have the potential to exhibit tuneable polaronic and ionic conductivity which makes them especially attractive for application as cathodes in solid-state batteries since both electronic and ionic conductivities are equally important in cathode processes (Huang *et al.*, 2001; Wang and Hong, 2007; Ma *et al.*, 2007; Riess, 1997).

The type and content of each component, the transition metal and alkali (or silver) oxide, in phosphate glasses determine the conduction mechanisms which enables controllable contributions of polaronic and ionic conductivity and gradual transition from predominantly polaronic to predominantly ionic transport with a fine variation in the glass composition. However, the presence of two types of charge carriers can have a negative impact on overall conductivity due to their mutual interactions resulting in the formation of neutral entities that do not participate in electrical transport. This effect, called the *Ion-Polaron Effect* (Bazan *et al.*, 1996) was first discovered in $\text{Li}_2\text{O}-\text{WO}_3-\text{P}_2\text{O}_5$ glasses where the authors showed that the substitution of WO_3 by Li_2O results in a deep minimum in electrical conductivity which can be attributed to a strong coupling of lithium ions and polarons. While ionic and polaronic conduction in phosphate glasses separately have been well detailed, their dependence or independence in the mixed systems seems to be in strong correlation with glass composition of the system under study (Montani and Frechero, 2003, 2006; di Prátula *et al.*, 2015; Garbarczyk *et al.*, 2000, 2003; Salman *et al.*, 2016; Jozwiak and Garbarczyk, 2005; Pavić *et al.*, 2018b; Nikolić *et al.*, 2018). Furthermore, studies on $\text{Na}_2\text{O}-\text{MoO}_3-\text{P}_2\text{O}_5$ (Bih *et al.*, 2001) and $\text{Li}_2\text{O}-\text{MoO}_3-\text{P}_2\text{O}_5$ (Bih *et al.*, 2000, 2008) glasses demonstrated that the conductivity mechanism is predominately polaronic in the alkali oxide poor region and mixed ionic-polaronic conductivity in the alkali oxide rich region. Special attention was paid to the determination of various factors that might influence complex ion-polaron transport, for example, the number density of ions versus polarons, their mobility as well as specific structural features of the glass network. The contribution of ionic conductivity was found to be very low in these glasses suggesting hindered mobility of alkali ions. Similarly, small mobility of alkali ions was identified in $\text{Na}_2\text{O}/\text{K}_2\text{O}/\text{Cs}_2\text{O}-\text{WO}_3-\text{P}_2\text{O}_5$ glasses (Barczyński, 2008) where DC conductivity was found to drastically decrease as up to 20 mol% alkali oxide is added at the expense of P_2O_5 . Such a conductivity trend was explained by the exclusion of a fraction of tungsten ions from the polaron hopping process when the alkali oxide is present in phosphate glass. Additionally, Šantić and Moguš-Milanković (2012) presented a detailed review on multicomponent glass systems based on iron phosphate glasses (IPG). By altering composition and preparation conditions, the electrical conductivity of glasses based on the $\text{Fe}_2\text{O}_3-\text{P}_2\text{O}_5$ system may vary over many orders of magnitude from 10^{-5} to 10^{-12} ($\Omega \text{ cm}$)⁻¹. A significant amount of alkali oxide (Na_2O) influences the conductivity mechanism in these glasses which changes from polaronic to ionic. An interesting observation is made regarding the contribution of silver cations in the mixed transport which is significantly higher if compared to the other monovalent cations. The high mobility of Ag^+ ions in phosphate-based glasses originates from their weak interactions with the phosphate glass network which make them loosely bound and easy to diffuse (Garbarczyk *et al.*, 2000, 2003; Bhattacharya *et al.*, 2006; Pavić *et al.*, 2018b).

Rare-Earth Ion Host Matrices

The start of solid-state lasers in the 1960s indicated a new era of phosphate glass research. Ever since then, phosphate-based glasses have been intensively investigated as rare-earth ion host matrices in laser systems, fibers, and optical lenses (Yamanaka *et al.*, 1981; Weber, 1990; Ehrt and Seeber, 1991; Hutchinson and Allik, 1992; Jiang *et al.*, 2000). Incorporation of rare-earth ions into the phosphate glass matrix is possible thanks to the very open and disordered phosphate matrix structure (Seneschal *et al.*, 2005). The laser-active rare-earth ions, like erbium, ytterbium, and neodymium, can be incorporated as dopants in a phosphate glass matrix in high concentrations without clustering (Hwang *et al.*, 2000). Among them, ytterbium is one of the most commonly used for the fabrication of phosphate glass for optoelectronic applications (Hutchinson and Allik, 1992; Pugliese *et al.*, 2016; Zervas and Codemard, 2014). Overall, the high solubility of rare-earth ions in the phosphate glass matrix, good chemical stability, and high optical damage threshold make phosphate glasses almost an ideal material for optical fibers.

In the field of optical lenses, phosphate glasses have found their application where the use of their low T_g helps in reducing the temperature and time of processing. On the other hand, their lower softening temperatures (500–800°C) present an advantage, but also a disadvantage since phosphate glass can suffer from thermal degradation under high-power operation. However, in comparison to silicate glasses, certain phosphate compositions have large rare-earth stimulated emission cross-sections and low thermo-optical coefficients which are desirable properties for high power laser applications (Weber, 1990).

Fluoride Phosphate/Fluorophosphate (FP) Glasses

Another important advantage of phosphate glasses is their ability to be melted with fluorides for the production of fluoride phosphate/fluorophosphate (FP) glasses for optical applications. Here, it is important to note that phosphate glasses with a glass network containing anions with phosphorus-fluorine bonds, such as the $(\text{PO}_3\text{F})^{2-}$ species, are called “fluorophosphate” glasses whereas those characterized with separate phosphate and fluoride anions in the glass network are known as “fluoride phosphate glasses” (Möncke and Eckert, 2019). The high fluorine-containing phosphate glasses are excellent for optical glasses with positive anomalous dispersion (Weber *et al.*, 1976; Ehrt, 2015, 2018; Möncke and Eckert, 2019). Moreover, FP glasses are good hosts for luminescent rare-earth ions, as they combine the optical properties of fluoride glasses with the higher mechanical and thermal stability of phosphate glasses (Galleani *et al.*, 2017).

Phosphate Dosimeters

Apart from their high ionic conductivity and related applicative importance, phosphate glasses doped with silver ions have found their application in dosimetry since they are RPL (radiophotoluminescence) dosimeters for the dose range from tens of μGy up to several hundreds of Gy (Piesch and Burghardt, 1994; Miyamoto *et al.*, 2011; Kodaira *et al.*, 2018; Sholom and McKeever, 2020). In particular, it was showed that dose-response curves of Ag^{2+} EPR signals and optical absorption of Ag-doped phosphate glass demonstrate a non-linear, monotonic increase with dose up to several hundreds of kGy which enables proper and precise calibration, thus qualifying these materials for the dosimetry for high-dose applications (Sholom and McKeever, 2020).

Phosphate Glasses for Immobilization of Nuclear Wastes

The development of a host for the immobilization of nuclear waste is focused on various vitreous waste forms including borosilicate, high silica, and phosphate glasses. High waste loading in a borosilicate melt is considered in most countries, except in Russia where aluminophosphate glasses have been approved since the late 1980s. Parameters affecting the waste glass performance, such as chemical durability, waste forms solubility, thermal and mechanical stability must be optimized relative to processing considerations such as melt temperature, waste solubility, melt corrosion, and volatility of hazardous species.

In the past, iron phosphate glasses have received considerable interest for use in vitrifying nuclear waste due to their exceptionally high chemical durability (DR). The value for DR at about $10^{-9} \text{ g cm}^{-2} \text{ day}^{-1}$, determined from the weight loss of bulk samples immersed in deionized water at 90°C , is obtained for $40\text{Fe}_2\text{O}_3\text{-}60\text{P}_2\text{O}_5$ mol% glass composition with O/P ratio close to 3.5. This implies that the pyrophosphate structure where the replacement of the easily hydrolyzed P–O–P bonds by the more chemically resistant P–O–Fe bonds is responsible for such good chemical durability. Such a dissolution rate is up to 100 times lower than that of window glass (Mesko *et al.*, 1998; Fang *et al.*, 2001; Yu *et al.*, 1997).

Other advantages for using phosphate glasses in vitrifying nuclear wastes are the low melting temperatures at about $\sim 1000^\circ\text{C}$ and high loading of wastes rich in Cs, Mo, U, and Cr which are poorly soluble in borosilicate glass (Day *et al.*, 1998). Also, iron phosphate glasses are particularly well suited for vitrifying wastes that contain appreciable amounts of sulfates, halides, and actinides. These components have a high solubility in iron phosphate melts, which diminish the obligatory pre-treatment of the wastes, in which the quantity of these components should be reduced to the level required for nuclear waste processes. Also, the retention of volatile species in an iron phosphate waste form is typically high, especially in those iron phosphate compositions that can be processed at lower temperatures. Thus, based on the research of iron phosphate glass waste form compositions it can be concluded that iron phosphate glass is a viable alternative for vitrifying many types of nuclear wastes.

Introduction

Glass as an Outstanding Material

Glass is a major material that takes an important part in our modern societies. It is more recent than metals – only a few thousand years – and takes advantage of its visible transparency, low cost and ability to be shaped in complex forms and huge sizes. Most common glass is referred to as soda lime silica glass, associating silica with the oxides of calcium and sodium.

While it has been extensively studied and developed, some scientific questions are still waiting for a satisfactory answer. Glass may be considered as a frozen liquid and thus it appears as a non-crystalline solid. The vitreous state is a particular state of matter that is intermediate between a crystal and a liquid.

At first glance, glass formation may appear as exceptional and restricted to a few chemical systems. Following numerous investigations and developments it appears now that glass formation is rather general, even though many materials cannot be obtained in the vitreous state. The occurrence of halide glasses – fluorides, chlorides, bromides, iodides – confirms this view. This chapter intends to describe the various glasses that belong to this group.

A Quick Historical Survey

Glasses based on beryllium fluoride BeF_2 were reported by Goldschmidt (1926) in the early part of the 20th century. A few years later multicomponent fluoroberyllate glasses were synthesized and characterized (Heyne, 1933). A major contribution was made by Sun (1949a) during the 1940s at Kodak Eastman laboratories. He also patented the first glasses based on aluminum fluoride. In addition he confirmed vitreous zinc chloride ZnCl_2 and reported vitreous silver halides AgCl , AgBr and AgI . Later vitreous zinc bromide was synthesized (Duffy and Ingram, 1983; Hu *et al.*, 1983). In the case of Be and Zn, the structural unit was found to be a tetrahedron: BeF_4 (Warren and Hill, 1934) and ZnCl_4 , which emphasizes the similarity with vitreous silica. The pioneering work of Winter (1955, 1957) must also be emphasized – various vitreous halides were reported: AlF_3 , SnCl_2 , PbBr_2 , PbI_2 .

The serendipitous discovery of the first fluorozirconate glasses in 1974 (Poulain *et al.*, 1975) was the starting point for very numerous studies on Heavy Metal Fluoride Glasses (HMFG) (Baldwin *et al.*, 1981; Comyns, 1989; Poulain, 1983; Aggarwal and Lu, 1991; France *et al.*, 1990; Katsuyama and Matsumura, 1989; Poulain, 2004, 2010). These investigations were stimulated by the prospects for ultralow optical losses that could lead to long haul, repeaterless fiber optic links (Shibata *et al.*, 1981; Gannon, 1980; France *et al.*, 1989). It appeared very attractive for submarine telecommunications and also for some defense projects. However, despite significant advances, this topic was largely abandoned after 1990. After major telecom labs discontinued the work, some small companies continued to manufacture fluoride glass optical fibers for infrared transmission. Since then, thousands of glass compositions have been identified and make the basis for further developments.

This chapter presents a review of halide glasses, either monohalides or polyhalides. It does not describe oxyhalide and chalcogenide glasses that are important groups and have been largely investigated.

The main features of halide glasses are often expressed by comparison to silica and borosilicate glasses. They may be summarized as follows:

- Low characteristic temperatures: melting, softening.
- Extended optical range, especially in the mid-infrared spectrum
- Limited mechanical properties: they appear as soft glasses
- Sensitivity to water: most chloride glasses are hygroscopic.
- Devitrification tendency.

Some of these properties open new fields of applications while others appear as limitations and raise technical problems.

Glass Compositions

Monocomponent Glasses

Several halides can exist in the vitreous form. They sometimes require fast quenching rates, and are obtained only as thin samples. This is not the case for BeF_2 and ZnCl_2 which can be cast as bulk samples. Sun (1946) reported silver halide glasses: AgCl , AgBr , AgI . Morey (1939) mentioned vitreous PbCl_2 , while Winter (1955, 1957) synthesized glass from AlF_3 , SnCl_2 , PbBr_2 and PbI_2 . ZnBr_2 glass was described later by Duffy and Ingram (1983) and Hu *et al.* (1983). It should be noted that these glasses could have

Table 1 Fluoroberyllate glass compositions (mol%)

BeF_2	AlF_3	MgF_2	CaF_2	SrF_2	BaF_2	PbF_2	LaF_3	LiF	KF
40	20	20				20			
20	30	5				45			
47	24		8.6				7.5	12.9	
33.5	22.9	21.1			22.5				
53								21	26
48	5	10	7.5						29.5
54.1	4.3	14	11.2	7	5		4.4		

been obtained under special conditions. The purity and the structure of the starting materials influence glass formation, and also the overall processing.

Monohalide Glasses

Fluoride glasses

Fluoroberyllates

Pure beryllium fluoride exists in the glassy form. It has been associated with other fluorides to improve glass quality and to adjust the physical and chemical properties. Various examples may be found in several review papers (Jahn, 1961; Rawson, 1967; Baldwin *et al.*, 1981).

Binary glasses have been reported in the BeF_2 -MF (M = Li, Na, K, Rb, Cs) and BeF_2 -M'F₂ (M' = Mg, Ca, Sr) systems. Alkali glasses are more stable than the alkaline earth glasses that require fast quenching to avoid crystallization. The extended work of K. H. Sun emphasizes the good compatibility of aluminum fluoride with BeF_2 to enhance glass formation. Typical glass compositions are shown in Table 1.

The main interest for fluoroberyllate glasses results from their low refractive index (close to 1.3), and non-linear refractive index (Weber *et al.*, 1978; Videau *et al.*, 1979). This feature is particularly attractive for the very high power lasers developed for nuclear fusion (Weber, 1980). This was probably the reason for the numerous works implemented in Russia in the late 1960s. Researchers at ATT Bell Labs have investigated the index dispersion of some fluoroberyllate glasses from which large NA (Numerical Aperture) fibers could be drawn.

The practical development of BeF_2 -based glasses was blocked by the toxicity of beryllium compounds. While toxicity rather affects beryllium oxide, no risk could be taken with fluoride. Another concern was hygroscopicity. Vitreous BeF_2 is hygroscopic, but multicomponent fluoroberyllates can withstand ambient atmosphere for many years (Sun, 1979). As a result, the interest of fluoroberyllate glasses is confined to fundamental research networks, or worse, in science museums!

Fluorozirconates

The first fluoride glasses based on zirconium tetrafluoride were discovered by Michel Poulain in March 1974, while trying to synthesize new crystalline complex fluorides (Poulain *et al.*, 1975). This initiated a range of studies on "Heavy Metal Fluoride Glasses". The limits for glass formation were determined first in the ZrF_4 - BaF_2 -NaF ternary system as shown in Fig. 1. It was a host for neodymium fluoride NdF_3 acting as an active element for emission at 1048 nm.

Further research confirmed the occurrence of glasses in numerous ternary systems such as ZrF_4 - BaF_2 -ThF₄ (Poulain *et al.*, 1977) and ZrF_4 - BaF_2 -NdF₃ (Lucas *et al.*, 1978) as shown in Fig. 2 as well as ZrF_4 - BaF_2 -LaF₃ (Lecoq and Poulain, 1979) (see Fig. 3), ZrF_4 - BaF_2 -UF₄ (Aliaga *et al.*, 1978), ZrF_4 - BaF_2 -CaF₂, ZrF_4 - BaF_2 -YF₃ and ZrF_4 - BaF_2 -GdF₃ (Mitachi, 1982). Two technical elements brought large advances in glass synthesis. The first one was the ammonium fluoride processing that allows preparation from oxides in open crucibles (Poulain and Lucas, 1978). This process leads to faster synthesis, larger samples at lower cost. It was only later that the authors realized that this process was already used by K.H. Sun 30 years earlier (Sun, 1949b). The second element was the discovery of the stabilizing effect of aluminum fluoride: a small addition of AlF_3 (<5 mol%) to a fluorozirconate glass melt was sufficient to reduce significantly the critical cooling rate required for obtaining crystal-free clear samples (Lecoq and Poulain, 1980a). Then quaternary glasses were reported in the ZrF_4 - BaF_2 - AlF_3 -MF_n (M = Li, Na, Ca, La, Y, Nd, Th) systems (Lecoq and Poulain 1980a,b). Lower cooling rate means larger bulk samples, and indeed, multikilogram glass windows could be cast. Incorporation of CsF was also studied (Kawamoto and Nohara, 1985). Ternary glasses were also investigated in the ZrF_4 -BiF₃-LiF or -NaF systems and glass formation areas are shown in Fig. 4.

The close similarity between zirconium and hafnium is well known to solid state chemists, and so it was expected to achieve glass formation in fluorohafnate systems. This was confirmed in the early stages of research. The glass forming area in the HfF_4 - BaF_2 -LaF₃ ternary system is shown in Fig. 5.

A large R & D effort was devoted to HMFG in the 1980s, mainly for their potential ultra low optical losses in the mid infrared range. Theoretical calculations lead to a minimum value of transmission losses ranging from 10^{-2} to 10^{-3} dB/km, depending on glass composition (Shibata *et al.*, 1981; Gannon, 1980; France *et al.*, 1989). Numerous laboratories and research centers were involved in this field: NRL and ATT in the USA, NTT, KDD, Hoya and Furukawa in Japan, BT in England, Siemens in Germany,

Alcatel and France Telecom in France, CSELT in Italy, Telecom Australia and Telebras in the southern hemisphere. In addition, subsequent funding from US Air Force and various state agencies worldwide allowed numerous academic laboratories to conduct fundamental and applied studies on HMFG, leading to a better understanding of the material properties and processing optimization. Specific symposia were organized and collections of the corresponding papers were published (Lucas and Moynihan, 1985; Drexhage *et al.*, 1987; Almeida, 1987; Yamane and Moynihan, 1988; Frischat and Moynihan, 1991; MacFarlane, 1991; Poignant *et al.*, 1993; Gan and MacFarlane, 1995; Bartholomew *et al.*, 1996). To date, the total number of scientific papers, patents and contributions largely exceeds 10,000. Publications on this subject, which provide a global view of the state of art of fluoride glasses include several books (Comyns, 1989; Aggarwal and Lu, 1991; France *et al.*, 1990), book chapters (Drexhage, 1985; Videau and Portier, 1985; Katsuyama and Matsumura, 1989; Sanghera *et al.*, 1998; Poulain, 2004, 2010) and review papers (Baldwin *et al.*, 1981; Poulain, 1983; Lucas, 1989).

The chemical composition of glasses can vary continuously within limits that are defined by the stability versus devitrification. This makes a significant difference with crystalline materials for which composition is ruled by stoichiometry, resulting in fixed physical properties: thermal, optical, mechanical... This provides an advantage for adjusting optimum characteristics of optical fibers, such as numerical aperture, optical transmission, chemical durability, thermal stability and strength. Addition of 4 mol% AlF_3 to $\text{ZrF}_4\text{-BaF}_2\text{-LaF}_3$ (ZBLA) and $\text{ZrF}_4\text{-BaF}_2\text{-NaF}$ (ZBNA) glasses increased their stability (see Fig. 6). Glass formation in the $\text{ZrF}_4\text{-BaF}_2\text{-YF}_3\text{-AlF}_3$ quaternary system is shown in Fig. 7. The combination of the ZBLA and ZBNA glasses leads to the ZBLAN ($\text{ZrF}_4\text{-BaF}_2\text{-LaF}_3\text{-AlF}_3\text{-NaF}$) glass which, in practice, most fluorozirconate glass components are made from and that have low critical cooling rates. Standard glass compositions based on ZrF_4 are given in Table 2.

Since fluoride glass components and optical fibers are commercially available (Le Verre Fluore, 2020; Fiberlabs, Inc., 2020; Thorlabs, 2020), scientific papers rather focus on physical properties and photonic applications, as described in the next section.

Fluoroaluminates

The first mention of fluoroaluminate glass may be found in a 1946 patent by K. H. Sun (Sun and Callear, 1949), largely known for his contributions to fluoroberylate glasses. He reported glass formation in the AlF_3 - PbF_2 - MgF_2 - SrF_2 system. However this did not attract much attention. The development of fluorozirconates provoked a growing interest for these glasses. A few years later, more systematic studies were performed. Glasses were prepared by quenching compositions in the AlF_3 - CaF_2 , AlF_3 - BaF_2 , AlF_3 - PbF_2 binary systems. Later, some more stable compositions were identified. They belong to the AlF_3 - BaF_2 - CaF_2 (Kanamori *et al.*, 1981), AlF_3 - BaF_2 - YF_3 - CaF_2 (Kanamori *et al.*, 1981) and AlF_3 - BaF_2 - YF_3 - ThF_4 (Poulain *et al.*, 1981a) systems (Fig. 8).

Samples more than 6 mm thick could be prepared in these quaternary systems, and rods could be drawn into fibers. Numerous other fluoroaluminate glasses have been synthesized in multicomponent systems including zinc, alkali, magnesium and rare earths (Poulain *et al.*, 1982b). A small amount of zirconium fluoride increases glass stability (Izumitani *et al.*, 1987). Commercial fluoroaluminate glass fibers are available (Fiberlabs, Inc., 2020; Le Verre Fluore, 2020). By comparison to fluorozirconates they offer a better chemical durability and a less extended transmission range in the mid IR. Fluoroaluminate glass compositions are reported in Table 3.

Fluoroindates

Not surprisingly, the discovery of the first fluoroindate glasses arose in laboratories specialized in solid state fluorides. The glass forming ability of InF_3 was reported almost simultaneously by Michel Poulain in March 1980 (Poulain *et al.*, 1981b), and a few days later by a team of researchers from Le Mans University (Miranday *et al.*, 1982). It was a few years before more systematic studies were implemented, in Le Mans, Bordeaux (Videau *et al.*, 1986) and Rennes universities (Poulain and Poulain, 1988; Messaddeq and Poulain, 1991; Poulain *et al.*, 1992a,b; Messaddeq *et al.*, 1993), and also in Japan (Nishii *et al.*, 1989). Fedorov *et al.* (2000) made an extended review of these glasses. It appears that the glass forming systems based on InF_3 are more numerous than those based on ZrF_4 . This is exemplified by the occurrence of several binary glasses associating InF_3 and various other fluorides: SrF_2 , BaF_2 , PbF_2 . However, to date, the thermal stability of the best fluoroindates is still lower than observed in optimized fluorozeirconates.

Systematic investigations were implemented with GaF_3 (Soufiane and Poulain, 1993) that exhibits a large chemical similarity with InF_3 . Numerous binary, ternary and multicomponent vitreous systems have been reported (Poulain, 2010). Gallium may replace indium in most fluoroindate glass compositions, and reversely InF_3 may substitute for GaF_3 in fluorogallate glasses. Such substitutions are likely to increase glass stability. In practice, fluorogallate glasses are not considered as a group distinct from fluoroindates.

Most standard fluoroindate glass compositions derive from the IZBS glass (mol%): 40 InF_3 , 20 ZnF_2 , 20 BaF_2 , 20 SrF_2 (Messaddeq and Poulain, 1991) with some variations, substitutions and additions (see Fig. 9). Typical vitreous systems based on IZBS with other fluorides are shown in Fig. 10, while various compositions are given in Table 4.

The synthesis of fluoroindate glasses appears more critical than that of fluorozeirconates mainly because devitrification is more difficult to control. In addition fining must take into account the oxidation-reduction processes that result from the two-oxidation states of indium (+3 and +1). The ammonium bifluoride processing may be used for glass synthesis, but the complete fluorination of the oxides requires time and temperature adjustments.

AZBZnYC	20	10	20		10	20			20	

Other fluoride compositions

The glass forming ability of various fluorides in multicomponent systems has been largely investigated and some compositions are given in **Table 5**. However most of them did not lead to practical developments for different reasons: devitrification tendency, cost, radioactivity, optical absorption.

A first group consists of glasses based on 3d transition metals: VF_3 , MnF_2 , FeF_3 , CoF_2 , NiF_2 , CuF_2 and ZnF_2 (Miranday *et al.*, 1981; Jacoboni *et al.*, 1983). They have been discovered and characterized in terms of structure and magnetic, electrical and luminescence properties at Le Mans university (Jacoboni, 1987).

By analogy with zirconium and hafnium tetrafluoride, it was expected that other tetrafluorides could also form glasses in multicomponent systems. Indeed various glasses may be obtained with ThF_4 and UF_4 . Others include UF_4 - BaF_2 - MF_2 - $M'F_3$ ($M = Mn, Cu, Zn$; $M' = V, Fe, Ga, In$), ThF_4 - BaF_2 - LnF_3 , (Lucas *et al.*, 1981) ThF_4 - BaF_2 - LiF (Poulain and Poulain, 1983). The ThF_4 - BaF_2 -(Yb,Y) F_3 - ZnF_2 systems have been largely investigated (Bouaggad *et al.*, 1987) as shown in **Fig. 11**. Note that a glass was also obtained in the TiF_4 - BaF_2 - NaF system as an analog to the first fluorozirconate glass.

Scandium fluoride ScF_3 forms glasses in the ScF_3 - BaF_2 - YF_3 system with possible incorporation of alkali fluoride (Poulain *et al.*, 1982a). Glasses based on VF_3 have also been reported.

Some divalent fluorides show a limited glass forming ability. This is the case for zinc fluoride that forms binary ZnF_2 - SrF_2 glasses (Messaddeq and Poulain, 1991) and ternary ZnF_2 - BaF_2 - LnF_3 ($Ln = La, Ce, Pr, Nd, Sm, Eu, Gd, Tb$) glasses (Fonteneau *et al.*, 1980). The limits of glass formation in each of these ternary systems are shown in **Fig. 12**. Multicomponent glasses have been studied in the ZnF_2 - BaF_2 - SrF_2 - YF_3 system (Jia *et al.*, 2018). Binary MnF_2 - BaF_2 glasses (Djouama *et al.*, 2007) and ternary ZnF_2 - CdF_2 - BaF_2 glasses have been observed (Matecki *et al.*, 1982) shown in **Fig. 13**. All these examples show that glass formation in fluoride systems is far from being an exception. There is little doubt that numerous new glasses could be observed in other multicomponent systems. The number of possibilities is still larger if several halides are associated.

Chloride glasses

There are specific features of chloride glasses in comparison with fluorides. First, characteristic temperatures (glass transition, softening and melting) are lower and come closer to room temperature. Most chlorides are hygroscopic and this makes synthesis

Fig. 9 Glass formation in the $\text{InF}_3\text{-ZnF}_2\text{-BaF}_2\text{-SrF}_2$ system (IZBS glass). Reproduced from Messaddeq, Y., Poulain, M.J., 1991. Stabilizing effect of indium in divalent fluoride glasses. *Materials Science Forum* 67–68, 161–168.

and characterization more difficult. This low chemical durability also limits possible applications. Some chloride glass compositions are given in [Table 6](#).

Glasses based on ZnCl_2

Vitreous zinc chloride ZnCl_2 is probably the best-known chloride glass. [Maier \(1925\)](#) was first to report it and studied its structure and some physical properties. Zinc chloride may be associated with alkali halides, but it appears that multicomponent glasses based on ZnCl_2 are rarely more stable against devitrification than ZnCl_2 itself. Glass synthesis requires special equipment to avoid moisture contamination. As shown in [Fig. 14](#) several vitreous systems have been investigated, for example $\text{ZnCl}_2\text{-KCl-MCl}_2$ where $M = \text{Mg, Ca, Sr, Ba}$.

Glasses based on CdCl_2

Cadmium is in the same column of the periodic table of elements as Zinc. It may be noted that glass progenitors often belong to the same column and this is an empirical criterion for glass formation. There are numerous examples: Si and Ge for oxides, Zr, Hf and Th for fluorides. Indeed cadmium chloride glasses have been reported ([Poulain et al., 1983](#)) in the $\text{CdCl}_2\text{-BaCl}_2\text{-MCl}$ ($M = \text{Na, K}$) system. These glass compositions, shown in [Fig. 15](#), are obtained by quenching as thin samples.

Glasses based on BiCl_3

Stable glasses have been described by [Angell and Ziegler \(1981\)](#) in the $\text{BiCl}_3\text{-KCl}$ binary system and also in the $\text{BiCl}_3\text{-KCl-NaCl}$ ternary system ([Ziegler and Angell, 1982](#)).

Glasses based on PbCl_2

Several authors have reported vitreous PbCl_2 ([Morey, 1939; Winter, 1955](#)). Multicomponent glasses have also been described including the $\text{PbCl}_2\text{-AgCl-CsCl}$ ternary system. It should be noted also that for $\text{CuCl-PbCl}_2\text{-RbCl}$ glasses the main glass progenitor seems to be CuCl ([Angell et al., 1985](#)).

Glasses based on ThCl_4

Chinese researchers have reported various chloride glasses based on thorium. As shown in [Fig. 16](#), several ternary systems have been investigated, for example $\text{ThCl}_4\text{-PbCl}_2\text{-CuCl}$, $\text{ThCl}_4\text{-PbCl}_2\text{-AgCl}$ and $\text{ThCl}_4\text{-PbCl}_2\text{-NaCl}$, $\text{ThCl}_4\text{-KCl-NaCl}$ ([Gan et al., 1985; Dai et al., 1988](#)).

TeX glasses

Glasses are formed in the Te-Cl system. The general formula is $\text{Te}_{(1-x)}\text{Cl}_x$ ($0.32 < x < 0.62$) ([Zhang et al., 1987](#)). While stoichiometry applies in halide glasses, it is no more the case in chalcogenide glasses in which Se-Se or Te-Te bonds will modify continuously the anion to cation ratio. In this respect the TeX glasses ($X = \text{halide or chalcogen}$) should rather be considered as chalcogenide glasses.

Fig. 10 Fluoroindate glass forming systems based on the IZBS glass. Reproduced from Messaddeq, Y., Delben, A., Boscolo, M., *et al.*, 1993. New fluoroindate glass compositions. *Journal of Non-Crystalline Solids* 161, 210–212. [https://doi.org/10.1016/0022-3093\(93\)90701-X](https://doi.org/10.1016/0022-3093(93)90701-X).

Bromide glasses

The chemical behavior of bromides is close to that of chlorides. Not surprisingly glass formation is observed with the same cations as in chloride glasses. Some bromide glass compositions are given in [Table 7](#).

Glasses based on ZnBr_2

Vitreous zinc bromide has been reported by [Duffy and Ingram \(1974, 1983\)](#) and was studied later by [Hu et al. \(1983\)](#). Incorporation of alkali bromides leads to binary and multicomponent bromide glasses. Several binary and ternary glasses have been reported: $\text{ZnBr}_2\text{-KBr}$; $\text{ZnBr}_2\text{-TlBr}$ ([Fuding, 1985](#)); $\text{ZnBr}_2\text{-CaBr}_2\text{-KBr}$ ([Kadono et al., 1988](#)); $\text{ZnBr}_2\text{-PbBr}_2\text{-MBr}$ ($\text{M}=\text{K}, \text{Rb}, \text{Cs-Tl}$) ([Nasu et al., 1985](#)); $\text{ZnBr}_2\text{-RbBr}$, $\text{ZnBr}_2\text{-RbBr}$, $\text{ZnBr}_2\text{-TlBr-GaBr}_3$ ([Nasu et al., 1985](#)). A typical vitreous diagram ($\text{ZnBr}_2\text{-PbBr}_2\text{-TlBr}$) is shown in [Fig. 17](#).

Glasses based on BiBr_3

Bromide glasses have been synthesized by [Angell and Ziegler \(1981\)](#) in the $\text{BiBr}_3\text{-KBr}$ binary system and compared with BiCl_3 -based glasses ([Ziegler and Angell, 1982](#)).

Glasses based on PbBr_2

Various bromide glasses have been synthesized with lead bromide as the major glass former. The $\text{PbBr}_2\text{-AgBr-CsBr}$ ternary system has been investigated. Other systems based on PbBr_2 as outlined above have also been reported, namely $\text{ZnBr}_2\text{-PbBr}_2\text{-MBr}$ ($\text{M}=\text{K}, \text{Rb}, \text{Cs-Tl}$) ([Nasu et al., 1985](#)) see [Fig. 17](#). Even though they include ZnBr_2 , lead bromide should be considered as the main glass progenitor.

Glasses based on CdBr_2

Ternary glasses have been reported in the $\text{CdBr}_2\text{-PbBr}_2\text{-TlBr}$ system ([Fuding, 1985](#)).

Glasses based on GaBr_3

While there is no report of glasses based on GaCl_3 , bromide glasses have been synthesized in the $\text{GaBr}_3\text{-NaBr}$ and $\text{GaBr}_3\text{-TlBr}$ binary systems ([Nasu et al., 1985](#)). More stable glasses are likely to exist in multicomponent combinations.

TeBr_x glasses

The Te-Br association also leads to glasses ([Zhang et al., 1987](#)). The vitreous domain is expressed by the general formula $\text{Te}_{(1-x)}\text{Br}_x$ ($0.3 < x < 0.5$). It is similar to the Te-Cl system.

Fig. 11 ThF₄-based fluoride glass systems. Reproduced from Poulain, M.A., Poulain, M.J., 1983. ThF₄ and LiF based glasses. *Journal of Non-Crystalline Solids, Preparation, Properties, and Structure of Special Glasses*, 56 (1), 57–61. [https://doi.org/10.1016/0022-3093\(83\)90446-5](https://doi.org/10.1016/0022-3093(83)90446-5). Fonteneau, G., Slim, H., Lucas, J., 1982. Stabilization of heavy metals fluoride glasses. *Journal of Non-Crystalline Solids* 50, 61–69.

Iodide Glasses

Some Iodide glass compositions are given in [Table 8](#).

Glasses based on ZnI₂

It does not seem that zinc iodide exists in the vitreous form. However binary glasses ZnI₂-KI and ZnI₂-TlI have been reported ([Nasu et al., 1985](#)).

Glasses based on CdI₂

Iodide glasses based on cadmium have been investigated in the CdI₂-KI-CsI and CdI₂-PbI₂-CsI ternary systems ([Byron and Gannon, 1983](#)).

Glasses based on PbI₂

[Cheng and Jin \(1995\)](#) reported a vitreous PbI₂, confirming the early report of [Winter \(1955\)](#). He also studied binary glasses xPbI₂-(1-x)AgI with 0.35 < x < 1 ([Cheng and Jin, 1995](#)). Multicomponent lead iodide glasses were not investigated but a large number of ternary glasses are likely to exist.

Other Iodides

There are common features between heavy halides, and this is largely observed in halide glasses. Then one could expect that iodide glasses could be found in chemical systems based on thorium, tellurium, bismuth and possibly gallium. Research in this field has been limited by experimental factors: hygroscopicity and low characteristic temperatures. More importantly, there were no real prospects for application for such materials.

Polyhalide glasses

Insofar as glasses are formed with all halides, it appeared logical to investigate chemical systems where different halides were combined. The aim of such research was to increase glass stability versus devitrification and to modify some physical properties, especially refractive index. There are two possible ways: either the incorporation of halides in standard glasses or new glass forming

Fig. 12 Zinc fluoride-based glass forming systems $\text{ZnF}_2\text{-BaF}_2\text{-LnF}_3$ ($\text{Ln} = \text{La, Ce, Pr, Nd, Sm, Eu, Gd, Tb}$). systems. The first approach corresponds to the incorporation of halides in fluorozirconate and fluoroaluminate glasses. The second one is exemplified by numerous fluorochloride glasses in chemical systems based on cadmium.

Fluorohalide Glasses

Incorporation of halides in fluorozirconates

Alkali chlorides MCl ($\text{M}=\text{Li}, \text{Na}, \text{K}, \text{Rb}, \text{Cs}$) have been combined with ZrF_4 - BaF_2 binary glasses. The corresponding ternary systems appear in **Fig. 18**. **Fig. 19** shows the existence of ZrF_4 - BaFCl and ZrF_4 - SrFCl binary glasses extending across the ternary system (Elyamani and Poulain, 1987). More complex glasses (Inoue and MacFarlane, 1987; Parker *et al.*, 1987; Tatsumisago *et al.*, 1988; Elyamani *et al.*, 1991) have also been reported. Some fluorochloride glass compositions are given in **Table 9**. The incorporation of bromides is difficult in open crucibles as atmospheric oxygen reacts with glass melt, releasing gaseous bromine. Fluorozirconate glasses containing lead iodide were investigated as materials for the storage of radioactive iodine (Poulain, 1981a,b).

Fluorochloride glasses

Cadmium fluorochloride glasses in systems such as $\text{CdCl}_2\text{-BaF}_2\text{-CdF}_2$, $\text{CdCl}_2\text{-BaF}_2\text{-NaF}$ etc... have been largely studied for their extended infrared transmission (Matecki *et al.*, 1983; Mouric *et al.*, 1985; Matecki *et al.*, 1987; Jha and Parker, 1991; Matecki and Poulain, 1992; Aitken *et al.*, 1993). Among numerous ternary systems of particular note are $\text{CdCl}_2\text{-BaF}_2\text{-CdF}_2$, $\text{CdCl}_2\text{-BaF}_2\text{-NaF}$ etc... These are shown in Fig. 20. Some fluorochloride glass compositions based on CdF_2 are given in Table 10. These glasses may be cast as thick samples (> 4 mm) and they are less sensitive to water than chloride glasses.

Manganese fluorochlorides are obtained in some ternary systems containing barium and sodium chlorides: $\text{MnF}_2\text{-BaCl}_2\text{-NaF}$; $\text{MnF}_2\text{-BaCl}_2\text{-NaCl}$; $\text{MnF}_2\text{-BaCl}_2\text{-ZnF}_2$; $\text{MnF}_2\text{-BaCl}_2\text{-MnCl}_2$ (Dai *et al.*, 1991).

Halides in other fluoride glasses

Chlorides may also be combined with fluoroaluminate glasses (Miura *et al.*, 1988, 1991) and also in fluoroindate glasses (Akella *et al.*, 1997).

Heavy halide glasses

Glasses based on Zn

Incorporation of bromides in zinc chloride has a stabilizing effect versus devitrification. This is exemplified by the following systems: ZnCl_2 - KBr - PbBr_2 , ZnCl_2 - ZnBr_2 - KX ($\text{X} = \text{Cl}, \text{Br}, \text{I}$), ZnCl_2 - KI - KBr . Similarly, the glass forming ability of zinc bromide is enhanced by other halides. Various glasses have been reported in binary and ternary systems: ZnBr_2 - TlBr - TlI ; ZnBr_2 - KCl ; ZnBr_2 - KI ; ZnBr_2 - TlCl ; ZnBr_2 - TlI .

Glasses based on Cd

Polyhalide glasses are observed in multicomponent systems based on cadmium. Among others significant systems are the CdX_2 - PbX_2 - KI ternary or the 30CdBr_2 - 43.5PbCl_2 - 26.5TlI glass (Fuding, 1985; Tatsumisago *et al.*, 1988).

Glasses based on Bi

The glass forming ability of bismuth halides increases in mixed halide combinations. Examples include the following systems: BiCl_3 - KBr , BiBr_3 - KI , BiBr_3 - TlBr - PbCl_2 .

Glasses based on Pb

Several studies were implemented on glasses based on lead chloride, bromide and iodide, firstly because of their stability against water: the solubility of lead halide is low, and as the glasses are usually prepared from aqueous solutions, then it may be expected that resulting glasses are not hygroscopic. The second reason lies in the existence of vitreous forms of PbBr_2 and PbI_2 . According to the “confusion principle”, multicomponent glasses should be more stable and withstand slower cooling rates.

The following vitreous systems have been identified: PbBr_2 - AgBr - CuCl - CsBr (Nasu *et al.*, 1985); PbBr_2 - CdBr_2 - TlI (Fuding, 1985), CdX_2 - PbX_2 - KI (Petrová *et al.*, 1989), PbCl_2 - CuCl - RbCl ; PbCl_2 - PbI_2 - CdCl_2 (Angell *et al.*, 1985), PbI_2 - PbBr_2 - KCl / KBr ; PbBr_2 - PbI_2 - CuCl or CuBr - KBr (Zhang *et al.*, 1992) ; PbI_2 - AgI - KCl / KBr (Cheng and Jin, 1995).

Miscellaneous

Angell *et al.* (1985) reported glasses based on silver halides and investigated their ionic conductivity. Typical glass compositions belong to the binary AgX-CsX (X=Cl,Br,I) (Lichkova *et al.*, 1988), for example 69AgX-31CsX (X = 0.45I + 0.55Br). Note that Nishii *et al.* (1985) obtained 10 mm thick samples for the 59AgX-39CsX-2PbX₂ (X = 0.38I + 0.62Br) (Angell *et al.*, 1985).59AgX-39CsX-2PbX₂.

Physical Properties

Composition-Property Relationships

There are strong correlations between chemical composition and physical properties. Halides – fluorine, chlorine, bromine, iodine – exhibit a high electronegativity, fluorine being the most electronegative element of the periodic table. The ionic character of the chemical bonding decreases from fluorides to iodides while the ionic radius increases from 135 nm for F[−] to 220 nm for I[−], resulting in lower bond strength. This directly influences thermal properties, namely glass transition and melting temperatures, and thermal expansion. In the same way, microhardness and fracture toughness decrease from fluorides to heavier halides.

Refractive index is ruled by the polarisability of the elements and the chemical bonds. In a general way the lowest refractive indices are expected in fluorides, while the larger ones should be observed in heavy halides, bromides and iodides. Non linear optical properties are usually correlated to refractive index and will follow the same trend.

Transparency appears as the most evident optical property. It is limited in the UV range by electronic transitions and in the infrared by lattice vibrations. Consequently fluorides will be more transparent in the UV spectrum, while iodides are expected to shift their IR absorption edge towards long wavelengths.

Optical Properties

UV Transmission

Fluoride glasses are transparent ranging from the UV spectrum to the mid-infrared. However the position of the absorption edges depends on the chemical composition which relates to the electronic band gap. The optimum situation is the association of fluorine anions and light cations. Glasses based on beryllium fluoride have the most extended UV transmission, to below 160 nm. Vitreous BeF₂ should be transparent at still smaller wavelengths on condition that it is extremely pure: traces of transition metals, hydroxyls and anionic oxygen have a drastic influence on UV absorption.

AlF₃-based glasses are good candidates for UV transmission. Unfortunately few data are available in this field. A first limitation relates to the difficulty in synthesizing ultra pure glasses with low content of transition metals. By comparison, the vapor phase processes used for silica make it easier. A second limitation arises from the heavy cations entering the glass composition: Ba, Sr, La, Y and even Ca and Na will reduce light transmission at short wavelengths. This limitation is difficult to overcome as stable fluoroaluminate glasses are obtained only in multicomponent systems. While BeF₂ incorporation would be beneficial in this respect, ZrF₄ is preferred in practice.

The UV edge of fluoro-zirconate glasses is shifted to longer wavelengths by comparison to fluoroberyllates and fluoroaluminates. However the development of optical fibers has led to very pure materials. Current ZBLAN windows are transparent beyond 210 nm. Further studies are needed to assess if it is the intrinsic limit.

Infrared transmission

The frequency corresponding to the maximum absorption in the infrared spectrum depends on bond strength and reduced mass of the M-F pair. It may be expressed by the following relation:

$$\nu = (1/2\pi)(k/\mu)^{1/2} \quad (1)$$

where k is strength constant, and μ is the reduced mass. Bond strength decreases as the ionic radius of the anion increases. Under these conditions, the position of the fundamental absorption peak is shifted to lower frequency when moving from fluorine to chlorine, bromine and iodine.

Fig. 21 Optical transmission range of standard fluoride glasses: fluoroaluminates (AFG), fluorozirconates (ZFG) and fluoroindates (IFG), compared with SiO_2 . Sample thickness: 3 mm. Reproduced from Poulain, M., 1984. *Les Verres Halogénés*. L'Actualité Chimique. 37–44.

In practice the position of the IR absorption edge is ruled by a multiphonon process and the corresponding frequency is several times larger than for the fundamental peak. It also depends on sample thickness. ZBLAN glass provides a significant example: IR edge is $6.5 \mu\text{m}$ for a 2 mm thick window (50% transmission) and $4.2 \mu\text{m}$ for an optical fiber (1 dB/m). By comparison fundamental absorption is observed around $18 \mu\text{m}$.

Simple rules may be used to assess the relative transmission of glasses. IR cut-off increases with ionic radius of both cation and anion. Also it is larger when cation charge is small. As a result it increases according to the following sequences:

Fig. 21 compares the spectral transmission of 3 mm thick samples of fluoride glasses: the IR edge for fluorozirconate glasses is shifted to smaller wavelength for fluoroaluminates and to larger wavelength for fluoroindates. The same behavior is observed for fluoride glass fibers. Heavy halide glasses –chlorides, bromides, iodides– transmit further in the IR spectrum. While this feature appears attractive, they are not used in practice because of physical limitations: hygroscopicity, low softening temperature, poor mechanical properties.

The potential for ultralow optical losses

Optical transmission of materials is limited by electronic transitions (Urbach tail) for short wavelength, and multiphonon absorption at long wavelength, in the IR spectrum. A third loss mechanism: Rayleigh scattering, takes place between these two edges. The global loss curve for a ZBLAN optical fiber exhibits a typical V shape that is illustrated in **Fig. 22**. The maximum transparency is observed at the bottom of this V curve. In the case of silica, theoretical losses are below 0.2 dB/km. This minimum depends on the material. It may be lower if the IR absorption edge is shifted toward long wavelength (Cozmuta *et al.*, 2020). This is the case for halide glasses, especially zinc chloride, as reported by Van Uiter (1979). Heavy Metal Fluoride Glasses (HMFG) also appear to be potential materials for ultralow optical losses. The theoretical minimum attenuation value of ZBLAN ranges between 10^{-2} and 10^{-3} dB/km at $\sim 3 \mu\text{m}$. Fluoroindates and cadmium fluorochloride glasses should exhibit still lower attenuation in the 3–4 μm range.

However the attenuation of the real optical glass fibers is larger than expected by theory. **Fig. 23** shows optical transmission (optical losses expressed in dB/km.) of commercial fluoride glass fibers based on AlF_3 , ZrF_4 and InF_3 . Attenuation is close to 1 dB/km for ZBLAN fibers. Limitations arise from the absorption induced by traces of impurities (Cr, Fe, Co, Ni, Cu) and by extrinsic scattering occurring from nucleation and interface defects. It has been emphasized that drawing fibers in microgravity could inhibit nucleation and improve ZBLAN fiber performance.

Refractive indices

The polarisability of the fluorine anion is very low, and consequently the refractive index of fluoride glasses is smaller than that of oxide glasses. Vitreous BeF_2 has the smallest refractive index of all glasses: 1.29. In multicomponent fluoride glasses that contain heavy cations (Sr, Ba, Y, La...) it is larger, and ranges from 1.4 in light fluoroaluminates to 1.5 in fluorozirconates and fluoroindates. Even when heavier cations, e.g., Pb or Bi, are incorporated, refractive index does not exceed 1.6. Gan (1995) gives a very good review of fluoride glass optical properties.

Fig. 22 Theoretical loss spectra (attenuation, dB/km) for a typical ZBLAN optical fiber (solid gray line) as function of wavelength (μm). The major components to the attenuation, UV (dotted line), IR (dashed gray line) and Rayleigh scattering (dash-dotted gray line) are shown. For reference, the theoretical loss spectra for silica optical fiber (dashed blue line) and that of industry best manufactured ZBLAN (solid red line) are also included. Fig. 24 Viscosity/Temperature diagram exemplifying the Strong $\rightarrow$ Fragile behavior in glass forming liquids. T^* is the temperature at which viscosity reaches 10^{12} Pa s. Reproduced from Angell, C.A., 1991. Relaxation in liquids, polymers and plastic crystals – Strong/fragile patterns and problems. *Journal of Non-Crystalline Solids* 131–133 (June), 13–31. [https://doi.org/10.1016/0022-3093\(91\)90266-9](https://doi.org/10.1016/0022-3093(91)90266-9). (Proceedings of the International Discussion Meeting on Relaxations in Complex Systems).

It is possible to calculate the value of the refractive index from its molar composition. The method was introduced by Sun (1947) and revised by Baldwin *et al.* (1981). It is currently used for adjusting the composition of core and cladding glasses for ZBLAN and fluorindate glass fibers.

As expected, refractive index increases in heavier halide glasses. Average n value is 1.5 for fluoride glasses while it reaches 1.6 for cadmium fluorochlorides. Few data are available for even heavier halide glasses. Measurements are made difficult by their hygroscopic character.

Thermal Properties

Characteristic temperatures

Glass scientists and engineers use several characteristic temperatures.

- Glass transition temperature T_g that corresponds to the solid/liquid transition.
- Softening temperature for which glass is deformed under its own weight.
- Temperature of crystallization onset, T_x .
- Crystallization temperature T_c , for which crystallization rate is a maximum.
- Melting temperature T_m which corresponds to the beginning of the melting process (first exothermic peak).
- Liquidus temperature T_l for which molten glass does not contain any crystal.

Thermal analysis (DTA and DSC) is an effective way to measure T_g , T_x , T_c and T_m . Because it concerns kinetic processes, their values depend on heating rate (or cooling rate) during the analysis. The usual value is 10 K/min.

Characteristic temperatures depend on glass composition. They are higher for fluorides and lower for chloride, bromide and iodide glasses. T_g ranges from 250 to 300°C for most fluoride glasses while is close to 50°C for BiCl₃ and BiBr₃ based glasses. Alkali ions (Li^+ , Na^+ , K^+) decrease T_g while fluoride glasses free of sodium and barium exhibit much larger T_g .

Crystallization temperatures T_x and T_c are observed somewhere between T_g and T_m . The difference $T_x - T_g$ reflects glass stability versus devitrification. Melting temperature of glasses is measured on reheating. As crystallization occurs first, thermal analysis records the melting temperature of the different crystalline phases resulting from the devitrification process. In multicomponent glasses several exothermic peaks are observed, and melting temperature cannot be determined unambiguously.

A reverse situation arises for liquidus temperature: T_l is unique, but it may be difficult to measure by thermal analysis. The empirical “two third” rule applies to most halide glasses. It is expressed by the following relation:

$$T_g/T_l = 2/3 \quad (2)$$

where temperatures are in Kelvin. This relation was first described by Kauzmann (1948) and has been observed in glass forming systems many times (Winter, 1955; Sakka and Mackenzie, 1971; Bruce, 1987).

Fig. 25 Viscosity as a function of temperature for fluorozirconate glasses with different sodium concentrations (0, 10 and 20 mol%). Reproduced from Hasz, W.C., Crichton, S.N., Moynihan, C.T., 1988. Viscosity temperature dependence of ZrF_4 -based melts. *Materials Science Forum* 32–33, 589–594.

Thermal expansion coefficient

The coefficient of thermal expansion CTE of halide glasses is larger than that of oxides. This higher coefficient is consistent with the differences in chemical bonding and formal ionic charges. For typical heavy metal fluoride glasses it ranges from 140 to $220 \times 10^{-7} \text{ K}^{-1}$. These values are larger than those for soda lime silica and other oxide glasses ($\sim 90 \times 10^{-7} \text{ K}^{-1}$). The CTE of BeF_2 that is isostructural with SiO_2 is $68 \times 10^{-7} \text{ K}^{-1}$. In chloride and bromide glasses CTE is larger and ranges from 250 to $400 \times 10^{-7} \text{ K}^{-1}$.

Note that there is an empirical relationship between thermal expansion and glass transition which was expressed by Van Uiter (1979):

$$\alpha \cdot T_g^2 = C_t \quad (3)$$

where T_g is expressed in Kelvin. According to Bruce (1987), the constant $C_t = 5.8$ for a set of fluoride glasses. Accordingly, elements that decrease T_g also increase CTE which is the case for alkali cations, barium and lead.

Heat capacity C_p

Heat capacity measurements have been reported only for fluorozirconate glasses. While the isostatic heat capacity C_p is expressed in $\text{J g}^{-1} \text{ K}^{-1}$, it is more convenient to consider the data on a per mole of atoms basis, that is: $C_p = C_p \cdot M$, where M is the average atomic weight of the glass. By so doing, it can be seen that the C_p values for ZBLA glass approach the Dulong-Petit limit of $3R$ ($24.9 \text{ J mol}^{-1} \text{ K}^{-1}$ for the vibrational heat capacity of solids). Similar results are observed for other fluorozirconate and fluorohafnate glasses (Bruce, 1987). The difference between heat capacity of solid glass below T_g and molten glass above T_g is also approximately constant ($14 \text{ J mol}^{-1} \text{ K}^{-1}$) (Bruce, 1987).

Viscosity

Several authors have investigated the viscosity of fluoride glasses. The behavior of vitreous BeF_2 can be compared to that of vitreous silica: on a logarithmic scale, the plot of viscosity vs reciprocal temperature T^{-1} is linear. In fact both BeF_2 and silica are exceptions. For most glasses the viscosity/temperature change deviates from the Arrhenius behavior. While industrial glasses follow the Talmann-Vogel-Fulcher law, the viscosity of fluoride glasses is still more non linear. They belong to the group of “fragile glasses” as introduced by Angel (1991) and exemplified by Fig. 24. A typical viscosity/temperature curve for fluorozirconate glasses with different sodium concentrations is reproduced in Fig. 25. Viscosity is very low around the liquidus temperature, less than 1 poise, and decreases sharply above glass transition. Devitrification makes viscosity measurements difficult for $\eta < 10^4$ poise.

Electrical Properties

In halide glasses electrons are engaged in chemical bonds, either ionic or partly covalent. Their mobility is very low and consequently they appear as insulating materials. However some ionic species may induce a significant ionic conductivity. This has been

extensively studied in fluoride glasses (Ravaine, 1985; Kavun *et al.*, 2018). Conduction is ensured by fluorine anions (Leroy *et al.*, 1978). It is different from the mechanism observed in oxide glasses in which alkali cations are mobile. No conduction has been observed with Na^+ ions (Reau *et al.*, 1990), while both F^- and Li^+ ions take part in electrical conduction in the $\text{ZrF}_4\text{-BaF}_2\text{-ThF}_4\text{-LiF}$ glasses (Reau *et al.*, 1985) and $\text{ZrF}_4\text{-BaF}_2\text{-LiF}$ glasses (Kawamoto *et al.*, 1990). The largest ionic conductivity has been reported in a fluoroindate glass.

In heavier halide glasses, the conduction process should be different: the mobility of chloride and bromide anions is very small, while alkali cations – Li^+ , Na^+ – could ensure some ionic conductivity. Studies require dry glove boxes because of hygroscopicity.

Devitrification

Glass formation

Several authors have tried to relate glass forming ability and chemical composition, on the basis of a disordered network or disordered packing. As glasses have been reported in covalent, ionic and metallic materials, it clearly does not depend on the nature of the chemical bonding.

Glass formation remains largely empirical. The so-called “confusion principle” has often been used as a guideline to find glass compositions more stable against devitrification. This principle states that glass stability increases with the number of glass components: a quaternary glass should be more stable than a ternary glass which is also more stable than a binary glass. A good example is observed in fluoride glasses: devitrification tendency decreases according to the sequence:

$$\text{ZB} < \text{ZBL} < \text{ZBLA} < \text{ZBLAN}$$

$\text{Z} = \text{ZrF}_4$; $\text{B} = \text{BaF}_2$; $\text{L} = \text{LaF}_3$; $\text{A} = \text{AlF}_3$; $\text{N} = \text{NaF}$

In oxide glasses, soda lime silica glass is much more stable than pure silica.

Kinetic studies

Numerous papers relate to the devitrification of HMFG, especially fluorozirconates (Poulain, 1992). Most of them use thermal analysis at temperatures higher than T_g to quantify the relative amount of crystalline phase. They are based on the Johnson-Mehl-Avrami-Kolmogorov (JMAK) relation (Avrami, 1938; Kolmogorov, 1939; Johnson and Mehl, 1939):

$$x = 1 - \exp(-kt)^n \quad (4)$$

Where x is the crystalline fraction, t is time, k is a constant that depends on nucleation and crystal growth and n is the Avrami exponent. This exponent can take different values depending on nucleation and growth mechanisms. This relation applies to an isothermal process. It is assumed that the constant k changes with temperature according to:

$$k = k_0 \exp(-E/RT) \quad (5)$$

Three kinetic parameters derive from the JMAK relation: n , E and k_0 . The physical meaning of activation energy E and frequency constant k_0 is not clear.

In a general way, the chemical composition of the crystalline phases resulting from devitrification is different from that of the parent glass. Apart from fluoride glasses, devitrification has also been studied in cadmium fluorochloride glasses.

Chemical Durability

Solubility in water

Chemical durability appears a major concern for halide glass development. Numerous studies have been implemented on fluorozirconate glasses (Simmons and Simmons, 1991). The critical reagent is water. Most papers are concerned with the behavior in aqueous solutions. When a piece of glass is immersed in water, it undergoes a slow chemical attack. As a result the surface is damaged and the pH of the solution drops (it becomes acidic). The rate of attack depends on pH and it increases rapidly as pH decreases: it is a catastrophic process! However the rate of attack is very low at pH 8. Bulk glass is stable in buffered solution at this pH (Simmons, 1987). In practice, it is essential to avoid liquid water staying on the glass surface. Simmons and Simmons (1991) have given an excellent review of the behavior of fluoride glasses in aqueous solutions in which it is noted that the rate of attack is slow. This allows the use of water for polishing fluoride bulk glasses and preforms.

Fluoroaluminate glasses are less corroded by water than ZBLAN glass (Poulain *et al.*, 1981a; Izumitani *et al.*, 1987). Fluoroindates are comparable with fluorozirconates. The sensitivity to water is larger in heavy halide glasses. Glasses based on ZnCl_2 , ZnBr_2 , BiCl_3 and BiBr_3 are soluble in water. In a general way, there is some correlation between the behavior of crystalline compounds and that of the glass they produce. Thus it is advantageous to incorporate significant amounts of insoluble halides. In this respect glasses based on lead and silver halides exhibit larger resistance to attack by water.

Atmospheric stability

Stability in ambient atmosphere is also controlled by water. Relative humidity is currently close to 50%. Deliquescent glasses such as vitreous ZnCl_2 attract water molecules resulting eventually in a liquid phase. Other sodium-rich glasses adsorb water molecules in wet atmosphere and form a hydrated layer.

Fig. 26 First structural model of fluorozirconate glass. Circles are for Barium ions. Polyhedra represent AlF_6 , ZrF_6 , ZrF_7 , ZrF_8 and LnF_8 groups. After Chanthanasinh, M., 1976. Synthèse de nouveaux verres fluorés à base de tétrafluorure de zirconium. Caractérisation et études spectroscopiques. Thèse de 3ème Cycle, Rennes, Rennes 1.

Fluoroaluminate and fluorozirconate glasses are stable in a normal atmosphere at room temperature for years, under the condition that water condensation is prevented. When temperature increases, a slow interaction occurs between the glass surface and water molecules which produces gaseous HF while OH^- ions are formed and diffuse through the glass surface. Water molecules are also activated under laser beam at $2.94\ \mu\text{m}$. The process has been studied for laser power transmission by ZBLAN glass fibers. Depending on laser power and pulse duration, fiber surface may be damaged.

Strong fluorinating reagents (F_2 , ClF_3) do not alter fluoride glass surfaces. Gaseous oxygen does not react with fluoride glasses, even above T_g . Reactive atmospheres have been used for glass processing. The purpose was to oxidize the reduced species in the glass melt. Reagents include CCl_4 (Robinson, 1985), SF_6 , NF_3 (Nakai *et al.*, 1986). In practice, dry air makes it simpler.

Structure

In contrast to crystalline phases, vitreous structure have long range disorder and there is no periodicity in the atomic arrangement. However, short range order is similar in crystals and in glass. Thus, in the first coordination shell, both interatomic distances and coordination numbers (CNs) are more or less the same in glass and in crystals. Differences are likely to occur in the second coordination shell, especially in multicomponent glasses. Structural information may be provided by various techniques such as XRD, neutron diffraction, XSAFS, XANES, and computer simulations.

Local Order

There is little doubt about local order in halide glasses, at least as far as glass formers are concerned. BeF_2 -based glasses are considered to be isostructural with silica glasses, with BeF_4 tetrahedra as the structural unit. In heavy metal fluoride glasses, the main coordination polyhedra are octahedra (AlF_6 , GaF_6 , InF_6 , ZnF_6 , LiF_6) or square antiprism and dodecahedra ZrF_8 , HfF_8 , ThF_8 .

Fig. 27 Bidimensional schematic of a fluorozirconate glass according to the random packing and the network models. After Poulain, M., 1989. Glass systems and structures. In: Comyns, A.E. (Ed.), *Fluoride Glasses*. Chichester, NY: John Wiley and Sons, pp. 11–48. (Critical Reports on Applied Chemistry 27).

In fact, solid state chemistry reports that coordination is largely ruled by the r/R ratio, in which r is the ionic radius of the cation and R the ionic radius of the anion. Large cations such as alkali and alkaline earth elements present in glass compositions are often reported as modifiers. Taking this r/R ratio into account, it should be expected that in fluorides the cations are surrounded by a rather large number of anions: from 8 to 10. This has been confirmed by structural studies (Coupé *et al.*, 1983; Simmons *et al.*, 1991).

In chloride glasses coordination number is 4 for Zn in ZnCl_2 and 6 for cadmium in fluorochloride glasses. In crystalline BiCl_3 , bismuth forms a pyramidal group with three near neighboring chlorine atoms at 0.25 nm and interactions with other chlorine at 0.32 nm. It may also be described as a pseudo tetrahedron $\text{BiCl}_3(\text{lp})$ in which lp represents the lone pair of $6s^2$ electrons attached to the trivalent bismuth. One may assume that the local environment is similar in bismuth halide glasses.

The Network Model

Glass structure is classically described on the basis of the Random network model. This concept was introduced by Zachariasen (1932), who deduced that vitrifying oxides should form small coordination polyhedra, triangles and tetrahedra. This model could also be applied to fluoroberyllate glasses. Heavy metal fluoride glasses are an exception to this approach, insofar as the CNs of Zr, Hf and Th are rather close to 8.

However it is possible to construct a network on the basis of square antiprisms and bipyramids sharing corners and edges. In this model larger cations such as Na^+ , Ba^{2+} are inserted in the voids of this network. A first example was given by Chanthanasinh (1976) shown in Fig. 26. It is consistent with further models of Kawamoto (1985) and Lucas (1989). In the structure of vitreous ZnCl_2 , Zn is tetrahedrally coordinated by chlorine atoms. At first glance it may appear similar to the structure of silica glass. However, it appears to be a random close packing of chlorine anions with zinc cations in tetrahedral holes (Desa *et al.*, 1982).

Disordered Packing and Lacunar Model

An alternative description of glass structure is a random packing of the most voluminous ions in which cations are inserted in sites existing in this structure. As large cations can take part in this packing, the only acceptable insertion sites are surrounded by anions (Poulain, 1981a,b). Fig. 27 shows a bidimensional schematic of the structure of a ZBLA glass, with the alternative network model (Poulain, 1989).

Fig. 28 2D representation of the structure of ZBLAN glass according to the lacunar model of the vitreous state. After Poulain, M., 1996. Vacancy model of glass. In: Proceedings of the 10th ISNOG symposium, B:10–15. Corning, NY.

The random packing description must be completed assuming that vacancies exist in this packing, creating packing faults (Poulain, 1996). These vacancies are simply missing ions and their distribution is bidimensional. As shown in Fig. 28, this leads to a cluster model. This model applies to halide glasses and also to metallic glasses. These two models – random network and lacunar – are complementary: the first one outlines the chemical bonding, while the second one puts the emphasis on volume and vacancy mobility; it also gives a physical meaning to glass transition.

Applications and Prospects

Optical transmission is the primary field for potential applications. Indeed it was investigated many years ago for fluoroberyllate glasses. The development of optical fibers has opened up further possibilities, and the reduced phonon energy of halide glasses offers prospects for new lasers. Nevertheless applications face practical problems as halide glasses are less robust than oxides and many are sensitive to water. As hygroscopicity is much higher with chlorides, bromides and iodides, most developments have focused on fluorides.

UV Optical Components

As pointed out above, fluoroberyllate glasses should be ideal for UV transmitting lenses and windows. Unfortunately the toxicity of Be and the purity requirements caused major problems that could not be overcome in view of the limited market size of such components. However, AlF_3 -based glasses are other candidates that have not been seriously investigated. They compete with ultrapure silica and fluoride single crystals (LiF). However, fluoride glasses are less sensitive than pure silica glass to photo-darkening (Jiang *et al.*, 2015).

Broadband Transmission Optical Fibers

Fluoride glass fibers are transparent over a very wide spectral range, from UV to mid infrared. At short wavelengths, extrinsic absorption may arise from transition metal impurities, especially Cr, Fe, Ni and Cu. Ideally, their concentrations in fluoride glasses should be in the ppb range (Ohishi *et al.*, 1983; France, 1990). Typical attenuation curves for the Visible and the IR spectrum are displayed in Fig. 23. Such fibers are used for remote spectroscopy and IR instrumentation.

Fig. 29 Supercontinuum emission obtained by pumping at 1550 nm in a ZBLAN glass fiber (red) and in a fluoroindate glass fiber (blue). Reproduced from Le Verre Fluore, 2020. Fluoride glass components. Available at: www.Leverrefluore.Com.

An important use of fluoride glass fibers concerns astronomy: several telescopes may be coupled in the K band (around 2.6 μm) through fiber links. Various astronomy projects have been successfully conducted using single mode ZBLAN fibers: FLUOR (Perrin *et al.*, 1995), OHANA (SPIE, 2002), GRAVITY (Blind *et al.*, 2015), SPIROU (Micheau *et al.*, 2012), SPIP.

Laser power transmission is also a promising field for fluoride glasses, especially at wavelengths larger than 2000 nm: fluoride fibers are more transparent than silica beyond 2100 nm. Coupling laser to fibers allows much more flexibility in practical use, especially for medical applications. This is the case for the Er:YAG laser at 2.94 μm . At this wavelength internal transmission exceeds 98% over 2 m. ZBLAN glass fibers withstand pulses in excess of 1 J.

Fiber Lasers

A fiber laser requires a pumping source, usually a laser diode, and a rare earth doped optical fiber. The advantages of this configuration are the following:

- long interaction length (by comparison to crystal lasers);
- high power density in fiber core;
- single mode laser beam (if the fiber is single mode);
- all solid state structure.

The laser cavity can be made using mirrors or preferentially Bragg Gratings inscribed in the fiber.

Numerous lasers have been constructed using rare earth doped fluoride fibers. The low phonon energy of the fluoride glass matrix influences the spectroscopic properties of the rare earth ions: the number of nearly purely radiative transitions increases significantly, and therefore so does the number of new wavelengths in a fiber laser form, both towards the blue and UV, and towards the mid IR (Allain *et al.*, 1989; Allen and Esterowitz, 1989; Carter *et al.*, 1992; Jackson, 2006; Pollnau and Jackson, 2008; Zhu and Peyghambarian, 2010; Hudson, 2014; Fortin *et al.*, 2015; Tyazhev *et al.*, 2020). Another advantage is clearly a higher solubility of rare-earth fluorides in the fluoride glass host, which results in higher rare-earth concentrations and therefore shorter fiber lasers.

The availability of IR pumping sources made possible visible emission by up-conversion. This was largely investigated in the 1990s and led to various blue, green and red experimental fiber lasers. Nowadays blue GaN laser diodes appear to be a more convenient choice to develop powerful visible lasers. Mid infrared lasers based on fluoride glass fibers are under development at 2.3 and 4.3 μm . Fiber lasers operating around 2.8 μm are already commercial, both as CW 10 W, and femtosecond lasers.

Optical amplification

Fiber-optic communication is mainly conducted in the wavelength region where optical fibers have small transmission losses. This low-loss wavelength region ranges from 1260 to 1625 nm, and is divided into five wavelength bands referred to as the O-, E-, S-, C- and L-bands. Current networks are designed for the 1.55 μm window (C band). However increasing data flow requires that other bands should be used: O-band (1260–1360 nm), E-band (1360–1460 nm), S-band (1460–1530 nm) and L-band (1565–1625 nm).

Telecommunication networks require special components for WDM (wavelength division multiplexing) and optical amplifiers for signal transmission and distribution. In the C-band Erbium-Doped Fiber Amplifiers (EDFA) are universally used. But silica fibers cannot be used for the other bands because their phonon energy is too large. Praseodymium doped fluoride fibers have been

studied for amplification in the E-band (Durteste *et al.*, 1991; Ohishi *et al.*, 1991; Yamada *et al.*, 1997) while thulium-doped fibers have been developed for optical amplification in the S-band (Luthi *et al.*, 2005).

Supercontinuum Sources

Supercontinuum generation has emerged as a specific field. It is formed when a collection of non-linear processes act together upon a pump beam in order to cause the large spectral broadening of the original pump beam. While materials exhibiting large non linearity would be favored, paradoxically, commercial devices use silica and fluoride glasses in which non linearity is very small. This is compensated by longer interaction length which is easily achieved in optical fibers. The two main requirements are low optical losses and high peak power in the pulsed pump laser.

Supercontinuum sources based on fluoride glasses were first reported by Xia *et al.* (2006, 2007) and this led to further investigations (Qin *et al.*, 2009; Théberge *et al.*, 2013; Kubat *et al.*, 2013; Swiderski, 2014; Fischbach *et al.*, 2015; Gauthier *et al.*, 2016; Michalska *et al.*, 2017). Their emission spectrum ranges from 0.7 to 4.1 and 4.8 μm , as can be seen in Fig. 29 which shows pumping at 1550 nm in ZBLAN and fluoroindate glass fibers. Their output power depends on pump power which may reach 30 W for experimental set-ups.

Supercontinuum sources may be considered as “white light” sources operating in the IR spectrum. They are finding applications in a diverse range of fields, including optical coherence tomography (OCT), fluorescence lifetime imaging, frequency combs, contactless chemical analysis, gas sensing and many others.

Other Applications

Because chlorides and bromides are hygroscopic, practical interest has focused on fluoride glasses. Bulk components have limited applications, and are used mainly for research purposes. Rare earth doped slabs and rods are used for fluorescent references and as active media for laser emission.

Undoped glass may be used for windows and lenses. For current applications, single crystals -CaF₂ or BaF₂- are preferred. However glasses offer the possibility of fine adjustment of refractive index. In addition, casting techniques allow large size and complex shapes. For example, a window 50 cm in diameter was made by Owens Corning for the NRL.

Cerium doped fluorohafnate glasses were studied as scintillating materials for the LHC (Large Hadron Collider) at CERN (Auffray *et al.*, 1996). However crystalline materials were preferred.

Summary

Glass formation is common in halide systems. Single halides exist in the vitreous state, for example BeF₂, ZnCl₂, ZnBr₂ and PbI₂. Other halides may vitrify by fast quenching, while more numerous halides act as glass progenitors in multicomponent systems:

- Fluorides: AlF₃, ZrF₄, HfF₄, GaF₃, InF₃, ScF₃, VF₃, CrF₃, FeF₃, ThF₄, UF₄, MnF₂, ZnF₂,
- Chlorides: CdCl₂, ThCl₄, BiCl₃, PbCl₂,
- Bromides: CdBr₂, BiBr₃, PbBr₂,
- Iodides: ZnI₂, CdI₂, PbI₂.

A number of polyhalide glasses have been investigated: fluorohalides and mixed heavy halides. Because of environmental problems, research on glasses based on beryllium and thorium was ended.

Fluoride glasses have been more extensively studied and developed. In a first step the prospect for long haul and low optical losses attracted significant interest and funding. Later, optical fibers appeared to be complementary to silica fibers for infrared transmission and fiber lasers.

In spite of their potential for infrared technologies, heavy halide glasses have been less developed, mainly because of their hygroscopicity. New encapsulation techniques could open promising perspectives.

Glass: Annealing and Tempering

Mathieu Hubert and Peter J Lezzi, Corning Research and Development Corporation, NY, United States

© 2021 Elsevier Inc. All rights reserved.

Introduction

Glass is a ubiquitous material in our everyday lives. Most glass products that surround us are produced via a melting process, starting from a mix of raw materials (batch) that is heated up to produce a molten liquid, homogenized, then rapidly cooled down and shaped into the desired form (Hubert, 2019). The rapid cool-down process generally experienced during the forming step can generate stresses in the material, which are detrimental to its mechanical performance. Manufacturers thus need to carry out specific steps to minimize the stresses in their products before releasing them on the market. Stresses in glass can be relieved via a controlled thermal treatment, called annealing. Annealing is therefore an integral part of the glass manufacturing process and is performed on most products found on the market.

On the other hand, under some specific controlled conditions, the formation of thermal stresses in the material can be used to an advantage to strengthen the glass article, using the so-called thermal tempering process.

For both annealing and tempering processes, control of the thermal history of a glass is thus critical. This chapter describes the key principles governing the annealing and tempering processes. To understand these principles, it is important to understand the evolution of glass and its structure as function of temperature. First, the relationship between glass viscosity and temperature will be described. Stresses, and the critical viscosity ranges at which they form and at which they can be released (annealed) will be detailed. Finally, the strategies by which glass manufacturers can take advantage of a controlled formation of stresses in glass products (tempering) will be described.

Viscosity Versus Temperature in Glass

Viscosity (η) is defined as the resistance of a material to deformation at a given rate. While it is expressed in Pa.s in the S.I. system, the preferred unit used in the glass-making world is the Poise (1 Pa.s = 10 poises, or 1 poise = 0.1 Pa.s).

The viscosity of a glass depends on its composition, and thus the temperatures at which the different process steps take place depend on the type of glass produced. Therefore, characteristic temperatures are better defined by a corresponding viscosity for each glass. The typical characteristic temperatures in the glass-making process and their corresponding viscosities are described in Table 1. Viscosity curves for different types of glasses, highlighting the impact of glass composition on its characteristic temperatures, are presented in Fig. 1.

The forming processes used to produce different types of glass articles – e.g., pressing or molding for bottles, drawing for fibers, etc., – are typically operated at different viscosities, upon cooling from the molten glass. During these processes, glass articles experience a rapid cooling rate, i.e., a rapid viscosity increase, spanning several orders of magnitude, while it goes from a liquid state at relatively low viscosities (~ 100 poises) at the melting temperature, to a solid state at lower temperatures. The transition between the liquid-like and solid-like behavior occurs at the so-called “glass transition” temperature.

At low viscosities (in the “liquid like state”), the glass structure can rearrange itself and relax constraints. At higher viscosities (lower temperatures, in the “solid like state”), the degrees of freedom to relax constraints reduce considerably, and it becomes impossible to release constraints. With the rapid changes in temperature and viscosity experienced by a glass article during the forming process, the glass is subject to thermal gradients and goes rapidly from low viscosities to higher viscosities, leading to the formation of thermal stresses. To relieve these stresses, the glass thus needs to be brought back to a temperature (= a viscosity) at which the glass structure has enough degrees of freedom to re-arrange itself and relax the constraints created. This process, called annealing, is typically carried out around the annealing point of the glass.

Stresses in Glass

In general, stresses in a material are detrimental to its mechanical properties (Guin, 2019). Glass makers thus need to reduce as much as possible the stresses in their products before putting them on the market. Stresses can arise from different sources and may be permanent or temporary.

The stresses generated in a glass are dependent on several factors, following the equation:

$$\sigma = \frac{E}{1 - \mu} \cdot \frac{\rho \cdot C_p}{\lambda} \cdot h \cdot d^2 \cdot b \quad (1)$$

Where σ is the stress generated in the product (in Pa), E is the Young's modulus of the glass (in Pa), α is its thermal expansion coefficient (in K^{-1}), μ its Poisson's ratio (dimensionless), ρ is the density of the glass (in $Kg\ m^{-3}$), C_p its specific heat (in $J\ Kg^{-1}\ K^{-1}$),

Table 1 Characteristic temperatures and corresponding viscosities in the glass-making process

Characteristic temperature	Corresponding viscosity	Definition
Melting point	10^1 Pa.s 10^2 Poise	In glass-making, temperature at which the viscosity is considered good for obtaining a well-fined melt with good homogeneity within the melting tank This does not correspond to a physical melting point as for crystals
Working point	10^3 Pa.s 10^4 Poise	Temperature/viscosity around which forming of articles typically occur. Often, the “working range” would be expressed, corresponding to a viscosity range of 10^2 to 10^6 Pa.s (10^3 to 10^7 Poise)
Softening point (Littleton point)	$10^{6.65}$ Pa.s $10^{7.65}$ Poise	Temperature at which the glass deforms under its own weight at a rate of 1 mm/min Defined by ASTM C338
Glass transition	$10^{-12-12.6}$ Pa.s $10^{-13-13.6}$ Poise	Temperature (or range of temperatures) where the glass transitions between a liquid-like material to a solid-like material
Annealing point	$10^{12.4}$ Pa.s $10^{13.4}$ Poise	Temperature at which the stresses generated during forming can be released by viscous relaxation within about 15 min
Strain point	$10^{13.5}$ Pa.s $10^{14.5}$ Poise	Temperature at which the stresses generated during cooling/forming can be released within about 15 h. Below this temperature, relieving the internal stresses is practically impossible

**Fig. 1** Viscosity curves for different glass families and characteristic temperatures commonly used in the glass-making industry (SLS = Soda-Lime-Silicate glass; LCD = Liquid Crystal Display glass).

λ is its thermal conductivity (in $\text{W m}^{-1} \text{K}^{-1}$), h is the cooling rate applied to the article (in K s^{-1}), d is the dimension/thickness of the article (in m), and b is a dimensionless shape factor (differs for flat glass versus tubes versus bottles/containers).

This equation clearly highlights that the generation of stresses in a glass is dependent both on the nature of the glass itself (its intrinsic properties) and on the process used (size/shape of the article and cooling rate applied). Therefore, for a similar thermal history (cooling rate):

- (1) For a given glass composition, the stresses generated may be different between articles of different shape/size.
- (2) For an article of a given size/shape, the stresses generated may be different if the composition of the glass is changed, i.e., if the intrinsic properties of the glass are different.

Fig. 2 Example of thermal gradient created upon cooling in a piece of glass.

These are very important considerations to keep in mind on the production of glass and annealing or tempering processes. These need to be adjusted to the type of glass produced, the type of article produced, and to the thermal history experienced by this article.

Thermal Stresses

During the forming process, glass typically experiences rapid cooling rates, during which it will contract. These cooling rates are often non uniform throughout the article, leading to the generation of thermal gradients in the product, and thus different parts of the product will contract at different rates, as illustrated in [Fig. 2](#), leading to different rates of expansion/contraction at different locations in the piece of glass. In general, the surface will cool down faster than the center of the material.

The thermal gradients thus formed lead to the formation of thermal stresses. As indicated in [Table 1](#), thermal stresses can be relieved at temperatures around the annealing point, and below the strain point, stresses in the material are virtually “frozen in” and cannot be relieved. The stresses created by a rapid, non-uniform cooling from above the annealing point to below the strain point of the glass are thus permanent stresses. These permanent stresses will remain in the product unless relieved using a controlled annealing process.

While permanent stresses cannot be formed below the strain point, temporary stresses can still be generated during the cooling of the glass from below that temperature. Despite their temporary nature, these stresses can lead to thermal shock and breakage of the glass if they exceed the maximum stress the glass can withstand.

Non-Thermal Stresses

Not all the sources of stresses in a glass are related to its thermal history. Defects such as inclusions (e.g., non-molten batch particles, crystals formed by devitrification of the melt, pieces of refractory from the melting tank, foreign particles from the forming process, etc.) typically have different thermal expansions than the glass matrix. Upon cooling, these defects will create some permanent stresses in the material. Inhomogeneities in the glass compositions, or cords, are another possible source of permanent stresses.

Contrary to thermal stresses, the stresses arising from defects or chemical inhomogeneities cannot be relieved by annealing.

Annealing Process

Basic Principles

The goal of the annealing process is to relieve the permanent stresses generated during the forming process of a glass article. As indicated in [Table 1](#), thermal stresses can be relieved at the so-called annealing point, and glass producers will carry out a controlled heat treatment, the annealing, in order to improve the mechanical performance of their product.

In the annealing process, the glass is first (re)heated up to a temperature slightly above its annealing point. The article needs to be kept at this temperature long enough to reach thermal equilibrium throughout the entire article. From the point where thermal equilibrium is achieved in the product and the stresses are relieved by visco-elastic relaxation, the key is to cool the article slow enough, down to below its strain point to avoid re-creating permanent thermal stresses. The cool-down process between the annealing and the strain point should thus be gradual, slow and uniform. Once the temperature in the article is below the strain point, the cooling rate can be increased, as from that point only temporary stresses can be generated. However, this cooling rate should not be too high in order to avoid breakage due to thermal shock.

Fig. 3 Typical temperature profile in an annealing lehr.

Annealing Lehrs

In most industrial glass production, the annealing step is performed in continuous annealing lehrs. The glass articles coming from the forming process are conveyed through the lehr, in which the temperature profile is designed following the principles described above. Annealing is usually followed by further post-processing and inspection steps. Glass producers must ensure that their lehr has a good thermal uniformity (e.g., left to right, top to bottom) to avoid creating thermal gradients throughout their product.

As indicated in Eq. (1), the stresses generated in a glass depend not only on its properties, but also on the shape of the article being manufactured, and annealing curves need to be designed specifically for each glass and product. Thicker products, or thicker parts in an article of variable thickness (for instance, the bottom and the mouth of a bottle are usually thicker than the main body) typically require longer times to reach thermal equilibrium, and this needs to be taken into account in order not to create stresses in these areas.

A typical annealing profile for a glass product is shown in Fig. 3, highlighting four main steps:

- (1) Rapid re-heating of the product: to bring it to a temperature slightly above the anneal point of the glass.
- (2) Dwell for thermal equilibration: critical to reach a homogeneous temperature throughout the entire article before cooling down.
- (3) Slow cool down: between the anneal point and the strain point. The cooling down needs to be uniform throughout the product during this step. Thicker articles (or thicker parts within an article) typically require slower cooling rates to avoid creating excessive thermal gradients.
- (4) Faster cool down: below the strain point, only temporary stresses can be created, and higher cooling rates can be applied. This faster cooling rate is usually applied for economic reasons, to shorten the overall time required for the annealing process (and thus shorten production times) in industrial production.

Glasses produced at the lab scale, or articles produced by glass artists are typically annealed in static furnaces (or *kilns*). The pieces of glass are introduced into a furnace that has been previously heated up to the annealing temperature. After closing the kiln, the heating is switched off, allowing for a slow cooling of the article down to room temperature. Care should be taken to not open the kiln too early in order to avoid the creation of stresses or thermal shocks in the product.

It should be noted that, during the annealing process, the glass article should not be heated up to a temperature too high above its annealing point, as reaching too low a viscosity could lead to a deformation of the product by viscous sagging.

Impact of Annealing on Glass Properties

As mentioned previously, the glass undergoes structural changes as it cools down from a liquid-like material to a solid-like material. Contrary to crystals, where the transition from liquid to solid is sharp and occurs at a very precise temperature (the melting point of the crystal), this transition is gradual in glass and occurs over a range of temperature around the glass transition temperature (Doremus, 1994). Due to this gradual transition, the cooling rate experienced by the glass can impact its structure. In other words, depending on the cooling rate applied, the glass structure may have more or less time to re-arrange before reaching a viscosity at which the structure is “frozen in” (i.e., below the strain point).

The thermal history of a glass (and cooling rate) will impact its properties, such as density (Narayanaswamy, 1971). The density of a given glass will increase with lower cooling rates. Optical properties, such as refractive index, are dependent on the density of

Fig. 4 Variation of the refractive index during cooling at constant rates. Reproduced from Lillie, H., Ritland, H., 1954. Fine annealing of optical glasses. *Journal of the American Ceramic Society* 37 (10), 466–473, with permission John Wiley and Sons

the glass, and are thus impacted by the thermal history of the glass. **Fig. 4** shows an example of the evolution of the refractive index of a glass as function of the cooling rate applied. With increased cooling rate, the glass at room temperature shows a lower refractive index (correlated to a lower density). While such a change in refractive index may not be an issue for many common everyday glass products (such as bottles or glassware), small variations of refractive index may be critical for optical applications (lenses, telescope mirrors), where very high optical homogeneity is required to avoid image distortions or chromatic aberrations. The annealing process is therefore all the more critical for optical glasses.

On the other hand, this dependence of the refractive index on the thermal history of the glass can be taken advantage of, as the refractive index of a product can be fine-tuned by tuning the annealing process applied to the glass. This strategy is used by optical glass manufacturers (Schott, 2019). It should be noted that the thermal history of the glass can also have an impact on some post-processing steps, such as ion-exchange (Zhang and Guo, 2020).

Quantification of the Stresses

Polarimeters (or polariscopes) can be used to measure the angle of rotation caused by passing polarized light (mono-directional) through an optically active material. Differences in the optical properties of this material will induce a difference in the rotation of this polarized light, which can be observed and quantified.

Perfect glasses are isotropic materials, meaning their properties (thermal, optical, etc.) are the same in all directions. However, the presence of stresses can lead to local deformations in the structure and thus to local changes in properties, notably in its refractive index, causing so-called birefringence. In other words, stresses present in the glass will have an impact on the way light travels through it, and this impact is proportional to the magnitude of the stress in the material.

Polariscopes can thus be used to observe and quantify stresses in glass articles (McKenzie and Hand, 1999). An example of glass products with high stresses and low stresses, observed using a polarimeter, is shown in **Fig. 5**.

Glass producers typically use this type of device as part of their standard inspection/quality control process (Redner, 1995). These are placed after the annealing lehrs and allow operators to identify and reject products with excessive internal stress.

Stresses in glass articles can be due to improper/insufficient annealing. Using polarimetry to evaluate stresses is thus particularly important when sending a new product through an annealing lehr to ensure it is properly set to minimize stresses. However, as mentioned previously, stresses can also be due to the presence of defects or chemical inhomogeneities in the products. These types of stresses cannot be relieved by annealing. When stresses are observed in the product, it is thus also important to carry out additional analyses (such as microscopic observations) to understand the root cause for the stresses and carry out proper troubleshooting.

Taking Advantage of Thermal Stresses

The goal of annealing is to reduce stresses in a glass article. As described previously, rapid cooling of a glass during its forming can lead to the formation of stresses, with uneven levels of stresses throughout articles. This inhomogeneity of the stress distribution within the article is one of the main sources of a reduction in mechanical properties, and the reason for a need for the annealing process.

Fig. 5 Observation of stresses by birefringence in glass jars. The jar on the left shows stresses at its center, while the jar on the right shows much lower stresses. Picture courtesy of ilis GmbH and Körber Pharma Inspection.

The strength of glass is primarily controlled by the existence of flaws on the surface due to processing and handling. These flaws will grow when placed under tension and can lead to the eventual failure of the glass article. Fortunately, it has been discovered that flaws which are under a compressive stress will not propagate, a concept which forms the basis for all known strengthening techniques for glass. Creating a compression layer at the surface of a glass product can be beneficial to its mechanical performance, provided this can be done in a homogeneous way. Such compression layer can be achieved via a controlled thermal treatment of the glass and the controlled formation of stresses, via the so-called tempering process. In the case of tempering, the formation of stresses is thus an advantage for the product.

Thermal Tempering

In thermal tempering, a glass product is heated to near but below the softening temperature and then rapidly quenched (Gardon, 1980). As a result, the glass will possess a lower surface temperature than the interior during cooling, as illustrated in Fig. 6. The temperature difference is maintained by sustained cooling until the surface of the glass cools to room temperature. As the center of the glass cools more slowly to room temperature it contracts to a smaller specific volume while the high specific volume of the surface layer remains unchanged. The difference in specific volume is in majority due to differences in the thermal expansion of the glass upon cooling, while to a lesser extent due to a difference in fictive temperature (the temperature at which the liquidus structure has become frozen in) between the surface and the bulk (Narayanaswamy, 1978).

Rapid quenching is required to maintain the necessary temperature differential through the thickness of the glass sheet which becomes increasingly difficult as the thickness of the glass sheet is reduced. The required quenching rates can be achieved through various means, including quenching the glass article directly into liquids such as water, oil, or molten salts, and solid contact quenching such as with metal or graphite plates. The most commonly used process for commercial products is convective quenching using enormous volumes of forced air. Due to the limitations of hot glass sheet conveyance and convective cooling, thermal tempering of commercial products has traditionally been limited to glasses of approximately 3 mm and thicker, although recent innovations in thin glass conveyance, have enabled some tempering of thinner glasses down to 2 mm.

The tempering process leads to a surface compressive layer that gives the glass improved strength over annealed glass. To a first approximation, the stress distribution in thermally tempered glass can be represented by a simple parabola, with the magnitude of the surface compressive stress approximately equal to twice the center tension (Barsom, 1968), as illustrated in Fig. 7. The magnitude of the residual stress is highly dependent on various factors including the thermal expansion curve of the glass – where glasses with higher CTE (coefficient of thermal expansion) produce higher stresses, the temperature from which the glass is quenched from – higher temperature producing higher stresses, and the quenching rate – faster quenching resulting in higher stresses.

Thermally tempered glass, sometimes called safety glass, is often applied in situations where a safe fracture behavior is required to prevent injury in the case of failure, being used to strengthen automobile side and rear windows, as well as household objects such as shower doors, coffee tables, etc. Thermally tempered glass also exhibits improved resistance to thermal shock and has found use in recent years in cookware, replacing the more expensive borosilicate glasses used in traditional products. It is desirable that when thermally tempered glass breaks, unlike annealed glass, it shatters into rock-salt like pieces which do not have sharp

Fig. 6 Schematic illustration of the rapid quenching of the surface during thermal tempering.

Fig. 7 (a) typical through-thickness stress profile in a tempered glass plate. (b) stress profile within the glass plate.

Fig. 8 A typical fracture pattern for a glass article achieving full temper.

edges or needle-like shapes (see [Fig. 8](#)). For this reason, it is required that all necessary cutting, grinding, etching, or finishing is done before the tempering process is performed.

The desired fracture behavior of tempered glass is sometimes referred to as “dicing” and occurs when the glass has achieved “full temper” ([Gardon, 1980](#)). The “dicing” threshold of tempered glass is an arbitrarily defined fracture behavior which can be considered safe to the end user in the event of glass failure. Standards exist worldwide such as ASTM C1048 and ANSI Z97.1 in the United States, EN12150-1 in Europe, GOST 5727-88 in Russia, JIS R 3206 in Japan, and GB 15763.2 in China. The standards are nearly identical across countries in that a fractured piece of tempered soda-lime glass is required to form at least 30–40 fragments

Fig. 9 The thermally tempered rear window of an automobile as photographed through a polarizing lens showing clear difference in stress due to the impingement of air jets during the initial quench. Picture adapted from Tal, E.J., 2020. Tempered Glass. Retrieved from Wikicommons: <https://commons.wikimedia.org/w/index.php?Curid=41083207>.

in an area of 50 mm $\times$ 50 mm (1.6 fragments per cm²) for thick glasses > 3 mm, with current Japanese standards requiring at least 60 fragments in the case of thinner glass (Timoshenko and Goodier, 1951; Gulati, 1997).

Therefore, the applicability to refer to a glass article as “tempered” does not solely depend on the stresses produced in the tempering process but is more dependent on the way the glass breaks. Glass articles processed in this manner which possess a residual compressive surface stress, but which do not fracture in the safe manner, are simply referred to as “heat-strengthened”.

It should be noted that strengthening by rapid quenching of the surfaces is the principle behind the famously strong Prince Rupert’s drops, obtained by pouring drops of molten glass in water, creating a strong compressive layer at their surface. These thermally tempered Prince Rupert’s drops can resist hammer blows, but when damaged, explode in very tiny particles; see also (Smarter Everyday, 2013).

Commercial Tempering Processes

In commercial tempered glass manufacturing lines, all necessary cutting, grinding, etching, or finishing is first done on the precursor glass articles – as such sharp contacts after tempering can result in breakage. The prepared glass articles are then fed onto ceramic rollers by continuous feeding or in a batch process in the loading zone. The rollers convey the glass articles into the tempering oven, which is held at a temperature near, but below, the softening temperature of the glass composition being tempered.

For typical soda-lime silicate glasses which are used in most tempered glass applications the oven would be in the range of 600–650°C. Once inside of the oven, the glass is held for a specified time until a uniform temperature is achieved throughout the glass thickness. In more sophisticated tempering lines, the rollers will periodically reverse directions to keep the glass moving at all times and prevent permanent sagging between the rollers. In some innovative new tempering lines, the hot glass is conveyed using an air bed instead of discrete rollers, which enables the glass to be heated to a higher temperature and safely conveyed to the quench – a technology which enables tempered glasses down to 2 mm (Vehmas *et al.*, 2015).

Once the glass reaches a uniform temperature, the glass is conveyed rapidly out of the opposite end of the furnace from which it entered. Upon exiting the furnace, the glass passes between an array of nozzles which momentarily blast high-pressure air onto the glass and rapidly cool the surfaces.

In fact, an observant driver will notice when wearing polarized sunglasses that they may be able to pick out the nozzle pattern used in thermal tempering when looking at the rear window of passing automobiles – an example of which is shown in Fig. 9. After the initial blast, the air pressure is then reduced, and the glass is oscillated under the nozzles to allow it to cool for safe handling, before being subsequently removed from the unloading zone. The finished glass articles are inspected for defects and occasionally taped and broken to confirm that they have achieved “full temper”.

It should be emphasized that the thermal tempering process is based on the controlled formation of stresses in a uniform manner throughout a glass article. This is very complex to achieve in product with a non-uniform thickness profile, such as traditional bottles, and is therefore mainly limited to glass products with uniform thickness profiles (windows, windshields, glass plates, etc.).

As mentioned previously, due to limitations in convection cooling rates and thermal gradients that can be achieved in thin glass articles, thermal tempering is typically limited to articles of thickness 3 mm and above. For thinner articles, e.g., cell phone screens, for which the thickness is typically below 1 mm, strengthening via creation of stress profiles can be obtained using chemical strengthening, or ion-exchange (not discussed here).

Summary

Stresses in glass articles have a strong impact on their mechanical performance. The forming process used during the manufacturing of these articles usually lead to the formation of stresses, non-uniformly distributed, weakening the product. These thermal stresses can be relieved from the glass by performing a controlled thermal treatment called annealing. In the annealing process, the product is heated up at a temperature slightly above its annealing point, and after thermal uniformity is reached, a slow cool down is carried out. Annealing allows one to minimize thermal stresses in the product, but will not reduce stresses arising from defects, inclusions or chemical inhomogeneities. The amount of residual stresses in a product is monitored using polariscopes. Stress measurement is an integral part of the quality control process for a large array of the glass products surrounding us in our everyday lives (windows, bottles, tableware, etc.).

While the thermal stresses formed during the forming process are undesirable, in certain conditions, a controlled formation of stresses via an additional thermal treatment can actually lead to an improvement in the mechanical performance of a product. Thermal tempering is the controlled formation of compressive stresses at the surface of glass products via a rapid quenching process after re-heating the glass close to its softening point. Due to practical limitation in cooling rates achievable, tempering is typically limited to products uniform in thickness, and thicker than 3 mm. Despite these limitations, tempered glass is a very common product on the market. When breaking, tempered glass articles shatter in a characteristic pattern with very small fragments, familiar to most who have witnessed windshields or other “safety glass” breaking event.

In both annealing and tempering processes, the intrinsic properties of the glass (based on its composition), its thermal history, and the size and shape of the glass article are critical parameters that all need to be considered by the glass producers.

Introduction

Glass is a key material of various applications, from windows to packaging containers to screens for electronic devices. Nevertheless, its employment is limited by its brittle nature; not only are oxide glasses characterized by poor mechanical strength but also they are not reliable due to the wide distribution of strength values. Surface flaws decrease the glass strength dramatically in spite of the theoretical strength being of the order of several gigapascals. **Fig. 1** shows the glass strength as a function of the surface crack size; a 1 μm surface defect decreases the strength from the gigapascal range to megapascals (Bradt, 2011; Bradt and Tressler, 2013). The development of stronger glasses could enable the production of lighter products and is, therefore, a key to the extension of glass utilization in new applications. Therefore, several techniques have been developed to improve glass strength: techniques such as etching, polishing and coating are used to increase glass strength by removing or inhibiting surface flaws, while thermal and chemical strengthening improve glass strength by reducing the negative impact of surface flaws by the creation of a residual surface compression layer as originally proposed in the 17th century through the “magical” Prince Rupert’s drop (Wondraczek *et al.*, 2011; Mauro, 2014; Varshneya, 2018).

Thermal tempering and chemical strengthening are the most effective methods for improving the mechanical resistance of glass (Karlsson *et al.*, 2010; Varshneya, 1994, 2018). Both techniques rely, basically, on the production of a compressive layer in the glass surface that shields the surface cracks and prevents their propagation; hence, the intensity of the surface compression and the thickness of the surface compression layer are crucial parameters. Thermal tempering has been abundantly used to reinforce glass used in automotive and architectural applications, furniture and kitchenware. Chemical strengthening has attracted much attention since the introduction of electronic devices with displays covered by a thin glass layer and the subject has renewed interest in recent times as demonstrated by several recent scientific publications (Varshneya, 2006, 2010a,b, 2018).

In the present chapter, the two strengthening methods, chemical strengthening and thermal tempering, are compared. The generation of surface compression and the kinetics of the processes are reviewed. Moreover, some non-conventional innovative methods for ion-exchange strengthening are mentioned.

Thermal Tempering

Thermal tempering is the most common technique for improving the mechanical strength of flat or almost-flat soda-lime silicate or borosilicate glass bodies. It is based on the generation of a surface compressive stress by a very rapid cooling of the glass body from a temperature well above the strain point (Shelby, 2005; Wondraczek *et al.*, 2011; Varshneya and Mauro, 2019; Sheth *et al.*, 2019).

The process consists of two fundamental stages: initially, the glass component is heated in a first chamber at the specified “tempering temperature”; then, it is quickly moved into a second chamber where is subjected to a very rapid cooling under the effect of compressed air forcedly blown on its surface. Here, since the surface cools down faster than the interior of the glass, a

Fig. 2 Residual stress distribution in glass subjected to chemical strengthening and thermal strengthening.

temperature gradient is created with the glass still being above the strain point, i.e., without the formation of significant stresses due to viscoelastic relaxation. However, as the surface reaches room temperature, the core is still warm, although being in a “solid-elastic” regime, and final cooling down to room temperature places it into tension while the surface goes into compression. The generated compressive stress, embracing about one fifth of the thickness of the glass on both surfaces, reinforces the area around surface flaws and improves the glass strength (Shelby, 2005; Karlsson *et al.*, 2010). A parabolic shape characterizes the stress profiles produced by thermal strengthening, resembling the temperature gradient created upon cooling (Shelby, 2005; Gardon, 1980; Varshneya, 1994). A typical residual stress profile produced by thermal tempering is shown in Fig. 2 (and compared to that generated by chemical strengthening) where it is clear that the core of the material is subjected to significant residual tensile stress.

Depending on the glass thickness and especially on the processing conditions (fundamentally, tempering temperature and cooling speed), the intensity of the residual stress (surface compression and corresponding core tension) can be varied. According to ASTM C1048-18 standard, if the surface compression is larger than 67 MPa the glass is defined as fully tempered or toughened; when the surface compression is between 24 and 52 MPa the glass is classified as heat strengthened (ASTM C1048 – 18, 2018). Correspondingly, with reference to the EN 12150 European norm, the characteristic bending strength is 120 MPa or 70 MPa for toughened and heat strengthened glass, respectively. In the former, due to the very intense tension in the core, when fracture occurs, the very large amount of strain energy can be dissipated by the formation of many surfaces and the glass shatters. The resulting small fragments are harmless (compared with big sharp glass fragments produced in annealed or heat strengthened glass) and toughened glass is therefore classified as safety glass (Veer *et al.*, 2009).

The deep surface compression produced by thermal tempering reinforces the area around large surface cracks. Nevertheless, there is a physical limit for the thickness of a glass to be thermally tempered, commonly around 2 mm; thinner glass cannot be strengthened to a significant extent due to the small temperature gradient which can be generated upon quenching. Moreover, thermal tempering is difficult to be applied to specimens with complex shape since the cooling effect generated by compressed air cannot be uniform on both surfaces for components which are essentially different from plate glass. Optical distortions represent an additional critical issue for thermally strengthened glass; they are generated because of the maintenance of the component at temperatures higher than the strain point before final quenching.

One final unusual aspect is the possibility for thermally toughened glasses to break spontaneously. Such phenomena can occur because of the presence of NiS inclusions in the glass core retained in a metastable state because of the very high cooling rates. If the transformation to the stable phase occurs, volume increases and this generates defects in the region under tensile stress which can lead to shattering (Kasper, 2019).

Chemical Strengthening

Chemical strengthening, also known as ion-exchange strengthening, is usually carried out by replacing smaller alkali ions in the glass, e.g., Li^+ and Na^+ , with larger alkali ions, e.g., K^+ , at a temperature below the glass transition temperature (Evers, 1969;

Varshneya, 2010a,b; Karlsson *et al.*, 2010; Mazzoldi *et al.*, 2013). Stuffing larger ions into the smaller alkali sites produces a compressive layer near the glass surface that reinforces the area around surface flaws and improves the mechanical strength of the glass. Although the compressive layer is smaller than the one produced by thermal strengthening, the surface compressive stress is larger (Fig. 2). Since the alkali ions are substituted during ion-exchange, chemical strengthening is usually applied to improve the strength of glasses containing significant amounts of alkali ions (Talimian and Sglavo, 2017a; Saunders and Kubichan, 1969; Gy, 2008; Varshneya, 2010a; Varshneya and Kreski, 2012). However, there are few reports claiming that this concept can be extended to replacing alkali-earth ions and improving the strength of alkali-free glasses (Mauro *et al.*, 2016).

Typical chemical strengthening techniques are based on the exchange of alkali ions. Larger ions, usually potassium, penetrate the glass surface and take the place of smaller alkalis, i.e., lithium or sodium. The “stuffing effect” accounts for the creation of compressive stresses which depend on the concentration of the invading ions. The process is typically carried out by placing the glass components in a molten salt bath (usually, KNO_3) for several hours at a temperature below the T_g . The thickness of the compressive layer, called case depth, depends on the depth of the ion-exchange layer which, in turn, depends on the inter-diffusion of alkalis.

Kinetics of the Chemical Reaction Between Salt and Glass

The following chemical reaction describes the chemical reaction between the glass surface and molten salt:

Garfinkel (1968) reported that the cation concentration at the glass surface, A_{glass}^+ , increases gradually with the concentration of ions in the salt, A_{salt}^+ , according to a sigmoid function; however, in practice, it is assumed that the equilibrium is established immediately after the immersion of glass in the molten salt. Araujo *et al.* explained the final concentration of alkali ions at the glass surface on a thermodynamic basis: the equilibrium between the glass surface and the salt bath is established when the difference of chemical potential of alkali ions in salt and glass is the same according to (Araujo, 2004; Araujo *et al.*, 2003; Araujo, 1993):

$$\mu_A^{\text{glass}} - \mu_A^{\text{bath}} = \mu_B^{\text{glass}} - \mu_B^{\text{bath}} \quad (2)$$

where μ_i^j is the chemical potential of elements of alkali cations in glass or salt and it is given by:

$$\mu_i^j = \frac{\partial(-kT \ln Q)}{\partial N_i} \quad (3)$$

where N_i is the number of ions, k is the Boltzmann constant and Q the partition function:

$$Q = q_A^{N_A} q_B^{N_B} \sum_{N_{AB}} \Omega(N_A, N_B, E(N_{AB})) \exp\left(\frac{-E(N_{AB})}{kT}\right) \quad (4)$$

where q_i is the partition function of the phase of interest (glass or salt) when it contains only ions of i . The mixing energy of different ions must also be considered when several ions are present. The summation part of Eq. (4) represents all possible values of interaction energy. Ω is the number of states of a particular interaction that can be estimated in simple systems; the detailed calculations can be found in previous work (Araujo, 2004; Fu and Mauro, 2013). By using the molar concentration of elements X_i and considering the bond strength changes in the salt and glass, the equilibrium constant, K_{eq} , is given by:

$$K_{\text{eq}} = \left(\frac{X_A^{\text{glass}} X_B^{\text{bath}}}{X_B^{\text{glass}} X_A^{\text{bath}}} \right) F(\text{bath}) F(\text{glass}) = \frac{q_A^{\text{glass}} q_B^{\text{bath}}}{q_B^{\text{glass}} q_A^{\text{bath}}} \quad (5)$$

where F is the Helmholtz free energy, which is a function of the interactions of atoms and ions in the salt bath and glass. In a system where the temperature and salt composition are not changing, the degree of freedom becomes zero. Therefore, there is a unique glass surface composition that, in turn, determines the chemical driving force for the diffusion of cations into the glass. It should be noted that the difference in chemical potentials is also affected by various parameters such as the polarization of ions in the salt (Garfinkel, 1968; Nordberg *et al.*, 1964).

The exchange of ions between the glass surface and interior parts occurs by the interdiffusion. Potassium ions diffuse inward, and glass alkalis, i.e., sodium ions, diffuse outward. During the ion-exchange process, the electric charge and mass remain balanced and, hence, the flux of ions is the first requirement of the process. Therefore, the total ions flux gradient should be zero to satisfy the charge neutrality:

$$\nabla \cdot J_A + \nabla \cdot J_B = 0 \quad (6)$$

Jost (1960) employed the flux gradient balance and described the mutual-diffusivity as a function of the number of ions in a small volume, N , and the diffusivity of every individual ion. The mutual diffusivity for a binary exchange can be written as:

$$\tilde{D} = \frac{D_A D_B}{N_A D_A + N_B D_B} \quad (7)$$

where D_A and D_B are the self-diffusion coefficients. The mutual-diffusivity is a function of the mobile ions ratio involved in ion-exchange. Therefore, mutual diffusivity is a function of distance from the surface (Araujo, 2004; Araujo *et al.*, 2003), and the diffusion equation can be written as

$$\frac{\partial C}{\partial x} = \frac{D_K}{1 - \alpha C} \left[\frac{\partial^2 C}{\partial x^2} + \frac{\alpha}{1 - \alpha C} \left(\frac{\partial C}{\partial x} \right)^2 \right] \quad (8)$$

where α depends on the ratio between the diffusion coefficient of ions, $\alpha = 1 - (D_K/D_{Na})$. Varshneya and Milberg (1974) have reported on the variable inter-diffusion coefficient in potassium-sodium ion-exchanged borosilicate glasses and the variation of the diffusion coefficient is related to the mixed alkali effect in silicate glass reported by Doremus (1974) and by Lacharme (1970). Ingram *et al.* (2000, 2005) have reported that a series of structural modifications account for the coefficient variations. Such variations have been usually reported for long ion-exchange treatments or particular glass compositions.

The produced concentration profiles using chemical strengthening can be fitted well by using a complementary error function where the diffusivity is considered constant (Varshneya, 2010a):

$$\frac{C(x, t) - C_i}{C_s - C_i} = \operatorname{erfc} \left(\frac{x}{2\sqrt{Dt}} \right) \quad (9)$$

where C_s is the concentration of potassium at the surface of ion-exchanged glass, C_i the potassium concentration of the as-received glass and t is the time. The inter-diffusion coefficient, D , depends on temperature following the Arrhenius' law:

$$D = D_0 \exp \left(\frac{-Q}{RT} \right) \quad (10)$$

where Q is the activation energy and R the perfect gas constant. The activation energy of ion-exchange can be measured by performing a series of ion-exchanges at various temperatures; the interdiffusion coefficient can be measured by fitting the produced concentration profiles using Eq. (9), and the activation energy can be determined using Eq. (10). Table 1 summarizes the interdiffusion coefficient of alkali ions in soda lime silica and alkali-silicate glasses. The activation energy of the alkali ions interdiffusion in silicate glasses is generally between 120 and 160 kJ mol⁻¹.

Fig. 3 shows the potassium concentrations profile in an alkali-borosilicate glass subjected to ion-exchange in pure potassium nitrate salt at 450 and 465°C; the profiles were fitted using Eq. (9) (Talimian and Sglavo, 2017b), assuming the diffusion coefficient to be composition independent. However, as pointed out above, in some conditions (e.g., for high temperature or long duration processes), Eq. (9) overestimates the depth of the ion-exchanged layer (as in the sample subjected to ion-exchange at 465°C). Therefore, more complex models should be used to fit the concentration profiles and estimate the diffusion coefficients:

Table 1 Typical interdiffusion coefficient, D , of alkali silicate and soda-lime silica glass at the ion exchange temperature

Diffusing ions	D (cm ² s ⁻¹)	
	20R ₂ O.80SiO ₂ (at 400°C)	Soda-lime-silica glass (at 530°C)
K ⁺	4.0×10^{-10}	1.2×10^{-11} (at 450°C)
Rb ⁺	4.5×10^{-10}	1.2×10^{-11}
Cs ⁺	1.1×10^{-11}	5.4×10^{-12}

Fig. 3 Potassium concentration vs. depth in sodium borosilicate glass subjected to Na/K ion-exchange for 4 h at 450°C and 465°C. Reproduced from Talimian, A., Sglavo, V.M., 2017b. Ion-exchange strengthening of borosilicate glass: Influence of salt impurities and treatment temperature. Journal of Non-Crystalline Solids 456, 12–21.

one possibility is to use the Boltzmann-Matano method based on microprobe chemical analysis as well as employing complex models available for inter-diffusion (Lupascu *et al.*, 1996).

Stress Generation by Ion-Exchange

Ion-exchange produces a layer in the glass surface whose molar volume is larger than the substrate due to the stuffed alkali ions; this results in the generation of surface compression. The build-up of compressive stress is assumed to be similar to the thermal stress in metals subjected to nitridation (Varshneya *et al.*, 2015; Varshneya, 2010a,b, 2006). Therefore, by using the thermo-elasticity analogy, the stress-strain relationship for an element located in the ion exchange layer (Fig. 4) where all alkali ions are replaced with the larger invading ions can be written as:

$$\begin{aligned}\varepsilon_{xx} &= \left(\frac{1}{E}\right) [\sigma_{xx} - \nu(\sigma_{yy} + \sigma_{zz})] + BC \\ \varepsilon_{yy} &= \left(\frac{1}{E}\right) [\sigma_{yy} - \nu(\sigma_{xx} + \sigma_{zz})] + BC \\ \varepsilon_{zz} &= \left(\frac{1}{E}\right) [\sigma_{zz} - \nu(\sigma_{yy} + \sigma_{xx})] + BC \\ \varepsilon_{xy} &= \frac{\sigma_{xy}}{G}; \varepsilon_{yz} = \frac{\sigma_{yz}}{G}; \varepsilon_{xz} = \frac{\sigma_{xz}}{G}\end{aligned}\quad (11)$$

where C is the concentration of invading ions (i.e., potassium), while E , G and ν are the Young's modulus, shear modulus and Poisson's ratio, respectively. B is the linear strain of glass per unit concentration change of alkali oxide, otherwise defined as linear network dilation coefficient (LNDC):

$$B = \frac{1}{3\Delta C} \frac{\Delta V}{V_0} \quad (12)$$

In a semi-infinite plate which is ion-exchanged in the x -direction, the plate is allowed to expand freely in such direction; therefore, the generated stress along the x -axis, σ_{xx} , is zero. The bulk glass constrains the surface layers; therefore, there is no strain in the y or z -axes, $\varepsilon_{yy} = \varepsilon_{zz} = 0$. By applying these boundary conditions to Eq. (11), the generated stress can be estimated as:

$$\sigma_{yy} = \sigma_{zz} = -\frac{BEC}{1-\nu} \quad (13)$$

The following equation was adopted to describe the generation of surface compression in glasses subjected to ion exchange as a function of the invading ions concentration, C , (Cooper and Krohn, 1969; Garfinkel and King, 1970):

$$[\sigma_{yy}]_x = [\sigma_{zz}]_x = -\frac{BEC}{1-\nu} + \left(\frac{BE}{\delta(1-\nu)}\right) \int_0^\delta C(x)dx \quad (14)$$

where δ is the thickness of the glass. The second term represents the balancing tension generated because of the compatibility of the exchanged layer to the uninfluenced bulk glass. It is clear that stress relaxation at high temperature is not considered in

Fig. 4 Schematic unit of a semi-infinite glass sheet subjected to ion exchange along x -axis. Only the generated stress in one direction is shown.

Fig. 5 Polariscope side view of chemically strengthened glass and the corresponding potassium concentration profile; the arrow shows the maximum compressive stress location. Reproduced from Gy, R., 2008. Ion exchange for glass strengthening. *Materials Science and Engineering: B* 149, 159–165.

Eq. (14). Cooper and Krohn (1969) have investigated such stress relaxation and the compressive stress produced by ion exchange after time t was estimated as:

$$\sigma_{yy}(x, t) = \frac{-BE}{1-\nu} \left(\frac{1}{\delta} \int_0^{t_1} R(t_1 - t) \left(\frac{\partial}{\partial t} \int_0^\delta C(x) dx \right) dt \right) \quad (15)$$

where R and t_1 are the normalized relaxation function and the ion exchange time, respectively. The first perception of the compression profile is that the compressive profile follows the concentration profile produced by ion exchange (Shen and Green, 2004a,b). Eq. (15) predicts that the maximum compression is produced at the glass surface. Fig. 5 shows the cross-section of a silicate glass subjected to chemical strengthening observed by polarized light, the typical potassium concentration profile being overlapped. The maximum compressive stress is located below the surface (Gy, 2008). The ion-exchanged layer is composed of a series of glass layers with slightly different composition, thus being characterized by different relaxation behavior which can be affected also by some salt bath impurities like water (Sane and Cooper, 1987; Lezzi *et al.*, 2014; Lezzi and Tomozawa, 2015; Seaman *et al.*, 2014; Tomozawa *et al.*, 2001).

Generally, the estimated surface compression is significantly larger than the measured and this is accounted for by the dilation glass network (Tandia *et al.*, 2012; Kreski *et al.*, 2012).

By assuming that the ion-exchanged glass has a molar volume similar to the compositionally equivalent as-melt glass, CEAM, LNDC is given by:

$$B = \left(\frac{1}{3C_0} \right) \ln \left(\frac{V_{CEAM}}{V_{Raw}} \right) \cong \frac{V_{CEAM} - V_{Raw}}{3V_{Raw}C_0} \quad (16)$$

where C_0 is the mole fraction of alkali glass in the exchanged layer and V_{Raw} the molar volume of the raw glass. The volume change is divided by three in order to obtain the linear dilation (Varshneya *et al.*, 2015). The estimated LNDC is usually about three to five times larger than the values measured from the stress profiles, this phenomenon being known as “dilation anomaly” (Varshneya *et al.*, 2015; Varshneya, 1975). Plastic deformation can occur upon stuffing larger ions into the glass and it is probably responsible for the observed differences (Varshneya, 2010b). Several efforts have been made to improve the understanding of network dilation

Fig. 6 Schematic illustration of structural modification of glass by breaking and reforming of bridging oxygen atoms during ion exchange. The bridging oxygen of a Q^4 group is stretched, weakened, broken and recombined with a Q^2 to accommodate a larger potassium cation. anomaly. Although the source of the dilation anomaly is controversial (Varshneya, 2010a), the glass relaxation, both structural and stress, are known to be responsible for such anomaly.

Temperature provides the required activation energy for stress relaxation; therefore, ion-exchange carried out for long times may result in the loss of the compressive stress (Varshneya *et al.*, 2015; Gutzow *et al.*, 2011; Shen *et al.*, 2003; Seaman *et al.*, 2014; Sane and Cooper, 1987). Therefore, stress relaxation is considered to be the main reason for the difference between the compressive stress profiles and potassium ion concentration profiles in samples (Tyagi and Varshneya, 1998; Varshneya *et al.*, 2015; Shen *et al.*, 2003). Several efforts have been made in order to formulate the correlation of residual stress and potassium concentration profiles. (Macrelli, 2018; Macrelli *et al.*, 2019, 2020). Nevertheless, even when stress relaxation due to viscous flow is considered in chemically strengthened glass (Varshneya, 2010a; Green, 2008), the surface compression is always significantly smaller than the estimates (Varshneya, 2016; Varshneya *et al.*, 2015). Varshneya (2016) has proposed a model to explain the reason for the limited residual stress. The model predicts that a series of structural changes occur in glass to host larger ions; this results in the production of smaller surface compression (Varshneya, 2016; Varshneya *et al.*, 2015; Ingram *et al.*, 2005). Cation-induced relaxation of the network, CIRON, has been proposed to describe the stress loss by short-range structural evolutions (Ingram *et al.*, 2005; Sglavo *et al.*, 2014). In such a model, the diffusion of cations into the glass occurs by breaking the bridging oxygens corresponding to Q^2 and Q^4 species and the formation of new Q^3 species. Fig. 6 shows a schematic illustration of structural modification in the diffusion pathway of potassium ions in a silicate glass (Ingram *et al.*, 2005, 2000). The glass layer with the new structure has a smaller volume; consequently, the resulting compression is smaller.

Although the ion-exchanged glass is more stable after the mentioned structural relaxation processes, its structure and, therefore, the volume is different from the glass with similar chemical composition produced by melting (Varshneya *et al.*, 2015; Varshneya, 2016). Therefore, the stress-free ion-exchanged glass is also called “forbidden glass” due to the different structure from the as-melted glass (Mauro and Loucks, 2009). It is worth mentioning that the structural evolution and stress relaxation of glass during ion exchange and chemical strengthening are open questions and need to be answered.

After the initial structural relaxation, the glass undergoes long-range structural relaxations that produce a glass structure similar to that which is obtained in a glass synthesized by melting the same chemical composition; these processes may last several years at low temperatures (Potuzak *et al.*, 2011; Lu *et al.*, 1999; Gutzow *et al.*, 2011). Although the stress loss includes various processes from very fast, picoseconds, to very slow, decades, the relaxation processes occurring in an intermediate time are of interest for chemical strengthening. Thus, viscous flow of glass has been considered responsible for stress relaxation, which is represented by mechanical models which essentially consist of Burger elements, a Maxwell and a Voigt-Kelvin element in series, attached to a rigid support (Varshneya, 2016; Tyagi and Varshneya, 1998; Sane and Cooper, 1987; Shen *et al.*, 2003).

Another approach to analyze the relaxation behavior is the stretched exponential model, proposed empirically by Kohlrausch (1847); it fits well the stress relaxation behavior of disordered and quenched molecular systems (Potuzak *et al.*, 2011; Lu *et al.*, 1999; Phillips, 1996). The property subject to relaxation, which is the surface stress, is a function of time:

$$\sigma_t^R = \sigma_0^R e^{-(t/\tau)^\gamma} \quad (17)$$

where σ_t^R and σ_0^R are the residual stress and the zero-time residual stress, respectively, t is time, τ the relaxation time, and γ the exponent factor which accounts for the non-Maxwellian behavior of the glass (Varshneya *et al.*, 2015). This function can also be used for structural relaxations in the frequency domain (Lu *et al.*, 1999; Phillips, 1996).

Eq. (17) has only two free parameters: the relaxation time and the stretching exponent, where $0 < \gamma \leq 1$. Low values of γ correspond to more complex relaxation mechanisms (Phillips, 1996; Gutzow *et al.*, 2011). Two particular values for γ are expected for inhomogeneous glassy systems: $\gamma = 0.6$ for short-range transitions such as stress relaxations and $\gamma = 0.43$ for long-range

Fig. 7 Surface compression in ion-exchanged soda lime silica glass as a function of chemical strengthening time; ion-exchange was performed at 425, 450 and 475°C. The experimental data are fitted with Eq. (17). Reproduced from Varshneya, A.K., Olson, G.A., Kreski, P.K., Gupta, P.K., 2015. Buildup and relaxation of stress in chemically strengthened glass. *Journal of Non-Crystalline Solids* 427, 91–97.

structural relaxations (Potuzak *et al.*, 2011). These numbers are known as “magic” values of glass relaxations; these numbers were deduced from the axiomatic diffusion trap model and had been validated using commercial glass specimens (Potuzak *et al.*, 2011; Phillips, 1996). Fig. 7 shows the residual compressive stress in soda-lime silica glass as a function of chemical tempering time and temperature; the experimental data is fitted using Eq. (17) with $\gamma = 0.43$.

Typically, the relaxation time lies between 10^5 and 10^7 s for the temperatures at which ion exchange is carried out. Moreover, the relaxation temperature is well fitted by the Vogel-Fulcher expression (Gutzow *et al.*, 2011; Varshneya, 2006; Doremus, 1994):

$$\tau(T) = \tau_0 e^{-Q \frac{T - T_0}{T_0}} \quad (18)$$

where T is the relaxation temperature, and T_0 and Q being Vogel-Fulcher parameters which are obtained by fitting the experimental data with Eq. (18).

For successful chemical strengthening, strong compressive stress with enough depth is a must to reinforce the surface around flaws and, consequently, increase the mechanical strength. Because of the diffusional nature of the process, producing the desired exchanged layer requires the glass to be subjected to elevated temperatures for several hours. Therefore, finding the critical parameters and their influences are the very first requirements of chemical strengthening of glass.

Chemical Tempering Methods

Four fundamental approaches can be used to perform chemical strengthening. In the most typical method glass is immersed in molten salt containing the invading alkali ions, i.e., Na^+ and K^+ ; alternatively, a mixed salts layer which partially melts at the ion exchange temperature can be applied on the glass surface; some processes can be carried out by using vapor-phase exchange; finally, electric field-assisted methods can be used (Karlsson *et al.*, 2010; Gy, 2008; Varshneya and Kreski, 2012; Varshneya, 2010a, 2018). Less common methods such as plasma, pressure or microwave-assisted methods have been advanced in the past which are not discussed here.

Chemical Tempering Using Molten Salt

The use of a molten salt is the most common industrial method for performing chemical strengthening. Glass components are placed for several hours in a steel vessel containing the molten salt. In most common practices silicate glasses containing enough alkalis, lithium or sodium, are immersed in molten potassium nitrate at a temperature below the glass strain point. Although there are several parameters influencing the ion-exchange process and, in turn, the efficiency of chemical strengthening, the basic factors that require to be optimized are:

- (1) temperature and time;
- (2) glass composition;
- (3) salt bath composition.

Glass composition

The chemical composition of the host glass has a major influence on the mobility of ions, generation of compression and stress relaxation. Since alkali ions are exchanged, the glass must contain a significant amount of alkalis such as lithium or sodium; therefore, alkali containing glasses are generally strengthened by chemical tempering. Aluminosilicate glasses show the highest

strength increase due to high alkali diffusivity and low-stress relaxation (Varshneya and Milberg, 1974; Morris *et al.*, 2004; Yoshida *et al.*, 2004; Varshneya and Spinelli, 2009; Xinwei and Rüdiger, 2011; Jiang *et al.*, 2013; Aaldenberg *et al.*, 2016). Although soda-lime silica glasses contain a larger amount of sodium than aluminosilicate glasses, the generated compressive stress is smaller due to the more rapid stress relaxation of soda-lime silica glass (Tool, 1948; Shen *et al.*, 2003; Shen and Green, 2004a,b; Doremus, 1974; Varshneya *et al.*, 2015). Alkali-borosilicate glass shows typically a moderate increase in the strength because of the limited concentration of alkali ions (Talimian and Sglavo, 2017a,b; Varshneya and Milberg, 1974).

Several efforts have been made to improve the efficiency of chemical strengthening by optimizing the glass composition. Deeper ion-exchanged layers can be produced in glasses containing two alkali oxides, i.e., sodium and potassium; however, this accelerates the stress relaxation. The strength of aluminosilicate glasses can be improved by increasing Al_2O_3 concentration until it reaches the same concentration as the alkali oxides. While increasing the amount of aluminum oxide has a small influence on the strengthening of soda lime silica glass, the concentrations of magnesium oxide and calcium oxide are important to improve the concentration of exchange ions. (Karlsson *et al.*, 2010; Gross, 2019; Tandia *et al.*, 2019) The addition of some oxides such as P_2O_5 and ZnO is claimed to be beneficial for chemical tempering; conversely, both lead and boron are known to have a negative influence. Effects of chemical composition on the glass properties are complex, particularly when several components are present. Hence, machine learning models have been applied in glass design; this can enable the development of new glass compositions with desired properties such as high diffusivity of alkali ions and high resistance to stress relaxation. (Tandia *et al.*, 2019; Onbaşı *et al.*, 2020).

Temperature and time

Inter-diffusion of alkali ions in the glass is the fundamental process for chemical tempering; therefore, time and temperature are two basic factors affecting the depth and the composition of the ion-exchanged layer. An appropriate temperature provides the required activation energy for the inter-diffusion of alkali ions and, therefore, the depth of the ion-exchanged layer can be tailored by performing ion-exchange at various temperatures. Fig. 8 shows potassium concentration profiles produced in soda-lime silica glass by performing ion exchange at 420, 460 and 490°C for 72 h.

Although deep ion-exchanged layers can be obtained at higher temperatures, processes carried out close to the strain point result in the relaxation of the generated surface compression (Shen *et al.*, 2003). Fig. 9 shows relaxation of compressive stress of 100 MPa in a soda-lime glass subjected to various temperatures. The surface compression reduces very rapidly (in a few minutes) at temperatures higher than 500°C that makes chemical strengthening essentially impractical.

The activation energy for inter-diffusion of alkali ions is of the order of 120–160 kJ mol^{-1} , while the activation energy of stress relaxation by viscous flow is in the range 300–600 kJ mol^{-1} (Varshneya and Mauro, 2019). Therefore, generally, performing ion-exchange at lower temperatures produces larger surface compression.

Salt bath composition and impurities

The composition of the salt bath has an important effect on the ion-exchange and the final properties of chemically strengthened glass. The salt composition affects the glass surface composition and, consequently, modifies the final properties of the glass. In fact, as the chemical potential of ions depends on their concentration in the salt bath, one would expect that any variation of molten salt bath composition should change the ion-exchange process. Fu and Mauro (2013) reported on the dependence of the mutual diffusion coefficient on glass and salt and showed that the contamination of potassium nitrate with limited amounts of sodium could be beneficial to the inter-diffusion process. Hassani and Sglavo (2019) have studied the effect of potassium nitrate systematically contaminated with sodium on the chemical strengthening of soda lime silica glass. Fig. 10 shows the surface compression produced by chemical strengthening in salt baths containing different amounts of sodium contamination. Interestingly, only relatively large amounts of sodium (in excess to 1 wt%) show an impact on surface compressions, the case depth appearing to be independent of sodium contamination.

Fig. 9 Normalized residual stress vs. time in soda-lime silica glass at various temperatures. Reproduced from Shen, J., Green, D.J., Tressler, R.E., Shelleman, D.L., 2003. Stress relaxation of a soda lime silicate glass below the glass transition temperature. *Journal of Non-Crystalline Solids* 324, 277–288.

Fig. 10 Surface compressive stress vs. the concentration of sodium impurity in potassium nitrate; the samples were subjected to ion exchange at 450°C for 4 h. Reproduced from Hassani, H., Sglavo, V.M., 2019. Effect of Na contamination on the chemical strengthening of soda-lime silicate float glass by ion-exchange in molten potassium nitrate. *Journal of Non-Crystalline Solids* 515, 143–148.

Conversely, alkaline earth cations, such as calcium or magnesium, have a detrimental impact on the chemical strengthening of glasses. Potassium nitrate salt bath contaminated by limited amounts of calcium or magnesium are considered “non-functional” since the resulting surface compression in the glass is much smaller than that produced using pure potassium nitrate (Kolitsch *et al.*, 1981; Sglavo, 2019; Sglavo *et al.*, 2017). Fig. 11 shows the impact of a few ppm of calcium on the surface compression of soda-lime silica glass subjected to ion-exchange at 450°C for 4 h. Calcium ions can block $\text{Na}^+ \text{-K}^+$ ion-exchange by taking the alkali site on the glass surface.

Water is another source of salt contamination in chemical strengthening; it can diffuse into the glass surface and affect the stress relaxation (Seaman *et al.*, 2014; Tomozawa *et al.*, 2001).

The increase of impurity concentration and contamination of salt may result in the deactivation of the salt bath after several ion-exchange processes; hence, a new salt bath should be used to obtain the desired properties. However, using pure salts has an economic drawback as well as environmental concerns about the disposal of the contaminated salt. Therefore, several solutions, such as using mixtures of old salts and pure potassium nitrate or the addition of some chemical, such as Si(OH)_4 , have been proposed.

Fig. 11 Surface compressive stress vs. calcium contamination of potassium nitrate; soda lime silica glass was subjected to ion exchange at 450°C for 4 h. Influence of salt bath calcium contamination on soda lime silicate glass chemical strengthening. *Journal of Non-Crystalline Solids* 458, 121–128.

Molten Salt-Free Chemical Strengthening

There is an interest in performing chemical strengthening without using molten salt due to the economic and environmental concerns about the use of large amounts of nitrate salts. Therefore, alternative methods, where salt-containing pastes, salt-spray and vapor deposition are employed, have been advanced (Sil'vestrovich *et al.*, 1990, 1984; Karlsson *et al.*, 2015, 2012; Sundberg *et al.*, 2019).

In one case, the glass surface is covered by a mixture of salts, typically potassium nitrate and potassium chloride, starting from a concentrated water suspension (salt-spray or salt paste techniques). The high viscosity of the salt mixture (where a residual solid is present) compared to pure potassium nitrate enables ion-exchange to be performed at a higher temperature than the conventional chemical strengthening using molten salt. Although non-conventional ion-exchange processes such as Na⁺-Rb⁺ or Na⁺-Cs⁺ can be produced by using the salt paste technique, the generation of surface compression is questionable because of fast stress relaxation at high temperatures (Karlsson *et al.*, 2012). Moreover, it is noteworthy that the depth of ion exchange layer (DOL) is considerably smaller than the average size of flaws on the glass surface (ca. 5 μm).

Vapor deposition is another molten salt-free technique for performing chemical strengthening. Here, a layer is deposited from a potassium- (or other elements) containing aerosol on the glass surface, and afterwards, ion-exchange is carried out by heat treatment at temperature below the glass strain point. High residual compressive stress can be achieved due to the relatively low ion exchange temperature; moreover, the vapor deposition and ion-exchange steps can be merged together in order to reduce the production cost (Karlsson *et al.*, 2015).

Electric field-assisted ion-exchange

Most research on chemical strengthening focuses on promoting the interdiffusion of alkali ions and the ability of the glass to be ion-exchange by optimizing the glass composition; however, there are some methods where the diffusion of alkali ions can be accelerated by the assistance of an external factor, such as ultrasonic waves, microwave radiation or electric fields. (Abou-El-Leil and Cooper, 1978; Kai and Jong, 2013; Talimian *et al.*, 2017, 2020; Shaisha and Cooper, 1981).

During electric-field assisted ion exchange (EF-IE), alkali ions are pushed in the direction of the applied E-field; it introduces a new driving force to the ion exchange process. Therefore, the produced ion exchange layer depends on both the applied electric field and the diffusion of ions. Fig. 12 shows potassium concentration profiles produced in soda-lime silica glass tubes by using electric field-assisted ion-exchange at 400°C. The concentration profiles resemble a step function, and a deep ion-exchanged layer with a DOL similar to conventional ion-exchange methods can be produced when a strong enough E-field is applied.

Fig. 13 shows Vickers indentations on the surface of SLS glass subjected to conventional Na⁺-K⁺ ion exchange and electric field-assisted ion exchange. There are no visible cracks surrounding the imprint in samples subjected to EF-IE, thus indicating that

Fig. 12 Potassium concentration profiles as a function of applied E-field. The concentration profiles were produced in soda lime silica glass using EF-IE. Reproduced from Talimian, A., Scardi, P., Sglavo, V.M., 2020. Sodium-caesium electric field assisted ion exchange in a mixed-alkali (Na, K) lime silicate glass. *Journal of Non-Crystalline Solids* 550, 120390.

EF-IE produces large compressive stress. The short duration of EF-IE and lower temperature in comparison to the conventional method suppresses stress relaxation and, therefore, larger surface compression is produced.

Moreover, EF-IE enables the replacement of small alkali ions in the glass, such as sodium, with significantly larger cations like cesium. Although the generated compressive stress by $\text{Na}^+ - \text{Cs}^+$ ion exchange is intuitively expected to be significantly larger than $\text{Na}^+ - \text{K}^+$, experimental results indicate that the residual stress is significantly smaller; the structural modifications of glass during ion-exchange account for the limited stress generation (Talimian *et al.*, 2017, 2020; Ingram *et al.*, 2000, 2005).

Fig. 13 Vickers indentation ($P = 500$ gf and $t: 15$ s) on soda lime silica glass: (a) as-received glass, (b) $\text{Na}^+ - \text{K}^+$ ion-exchanged at 400°C for 5 min, (c) $\text{Na}^+ - \text{Cs}^+$ ion exchanged using EF-IE ($E = 2000 \text{ V cm}^{-1}$, $t = 5$ min). Reproduced from Talimian, A., Scardi, P., Sglavo, V.M., 2020. Sodium-caesium electric field assisted ion exchange in a mixed-alkali (Na, K) lime silicate glass. *Journal of Non-Crystalline Solids* 550, 120390.

In order to perform successful ion exchange, the glass article should act as an insulator between the different poles of the electric field and this raises technical issues concerning insulation at high temperatures. In addition, non-uniform exchange of ions on the glass surface may result in inhomogeneous residual stress, which results in strength degradation. Hence, electric field-assisted ion exchange strengthening of glass has remained less practical so far.

Engineered stress profiles

The strengthening of glass by producing Engineered Stress Profiles, ESP, is a relatively recent method for improving the mechanical properties of glass (Glass *et al.*, 2000; Green, 2003; Abrams, 2004; Green, 2008). ESP glasses have a residual stress profile which increases from the surface (where it is almost zero) until it reaches a maximum at a definite depth; thus the apparent fracture toughness increases with the crack depth (Sglavo *et al.*, 2004a). Because of this, surface cracks can grow in a stable way before final failure thus making the strength independent of the surface flaw size (Glass *et al.*, 2000; Abrams *et al.*, 2003; Abrams, 2004; Sglavo *et al.*, 2007). Furthermore, multiple surface cracks appear before failure, which act as an initial warning (Abrams, 2004; Green, 2008; Sglavo *et al.*, 2004b).

ESP can be produced in glass by a double ion-exchange process. A deep ion-exchanged layer is produced by a long normal chemical strengthening process. Then, a second step is carried out by a short inverse ion-exchange, such as immersing the ion-exchanged glass in a molten salt comprising of $\text{KNO}_3/\text{NaNO}_3$ for a few minutes (Sglavo and Green, 2004; Green, 2003).

Summary

Thermal tempering and chemical strengthening are two common methods for improving the mechanical properties of glass. Both techniques are based on the production of a residual surface compression which shields surface defects and cracks; therefore, the intensity of surface compression and its depth are of crucial importance for successful strengthening.

In spite of the efforts made to study the generation of compressive stress and influential parameters in chemical strengthening, the understanding is still rudimentary. The effect of temperature and time on strengthening has been extensively studied, but the effects of other factors such as glass composition and salt impurities still require further investigation. Alternative ion-exchange methods, such as electric field-assisted or molten salt-free approaches, require further study in order to improve the strengthening efficiency.

Definition of Glass

In everyday language the term glass designates a transparent substance, possessing the properties of hardness, rigidity, and brittleness, and, apart from transparency, these are the typical properties one normally associates with a solid. Glass also possesses a number of properties which are characteristic of the liquid state, and classification of glass as a liquid of very high viscosity rather than a solid would be in accordance with modern views (McMillan, 1979). Unlike crystals, glass does not have a sharp melting point, but like crystalline solids, glasses show elasticity (Paul, 1990).

Due to the complexity of the structure of glass, it is not altogether surprising that an exact, all-encompassing definition for glass remains elusive, and instead a number of definitions have been suggested over the years. A more generally accepted definition is that offered by ASTM (C162) which states “a glass is an inorganic product of fusion which has cooled to a rigid condition without crystallization.” However, the ASTM definition limits the definition of glass to inorganic constituents, which fails to explain organic and molecular glasses that now represent a rapidly growing area of study (Varshneya and Mauro, 2010; Doremus, 1994). Newly developed solution based sol–gel synthesis of oxide materials occurs at much lower temperature than traditional solid-state fusion processes and also allows powderless non-fusion processing of glasses. X-ray and electronic diffraction studies have shown that glass lacks long-range periodic atomic arrangement, and every type of glass exhibits time-dependent glass transformation behavior (Paul, 1990; Shelby and Lopes, 2005). Pointing this out, Varshneya and Mauro (2010) suggest a scientific definition of glass as “a solid having a non-crystalline structure, which continuously converts to a liquid upon heating.” Zarzycki (1991) favors a more simplified definition: “a glass is a non-crystalline solid exhibiting the phenomenon of glass transition.” Thereby this definition also conveniently separates non-crystalline materials into the categories of glass and amorphous materials.

The Glass Transition

Glass is usually formed on solidification from the melting stage. The cooling is so rapid that crystallization does not have the time to occur. With a further decrease in temperature, viscosity continues to increase, resulting in a progressive freezing of the liquid to its final solidification. The relationship between crystal, liquid, and glass can be explained by means of specific volume as a function of temperature (see Figure 1).

On cooling from an elevated temperature (T_s), at the point of solidification (or freezing), two phenomena may occur. There is either a discontinuous change in volume at the melting point if the liquid crystallizes, or crystallization is avoided and liquid passes to a supercooled state (between T_s and T_g) and the volume of the liquid decreases steadily until there is a decrease in the expansion coefficient at a range in temperature called the glass transformation range. Below this temperature range the glass structure does not relax and the expansion coefficient is usually same as that for the crystalline solid. The intersection between the curve of the glassy state and that for the supercooled liquid is known as the glass transition temperature, T_g (Kingery and Uhlmann *et al.*, 1976). This T_g varies with cooling rate (see Figure 1) and thus it is more accurate to call it a transformation range rather than a fixed point (Lancry and Régnier *et al.*, 2012). The glass transition temperature increases with increasing cooling rate. The specific volume of the formed glass follows this same trend, increasing with increased cooling rate. With a slower cooling rate the time available for the structure to relax increases and the supercooled liquid persists to a lower temperature resulting in a higher-density glass.

Structure of Glass

A number of models exist to describe the structure of glass, including a random network model, a crystallite model, as well as other structural models. Random network theory, which is originally based on the ideas of Zachariasen, is the most common model used for explaining glass structure. Here only the random network model is briefly discussed and readers are referred to the following literature for details of other models (Zarzycki, 1991; Kingery *et al.*, 1976; Uhlmann and Kreidl, 1983; Doremus, 1994).

Figure 1 Schematic specific volume–temperature relationships for crystallization and glass formation. 1: liquid, 2: supercooled liquid, 3: glass on fast cooling, 4: glass on slow cooling, 5: crystal; T_s : melting temperature, T_g : glass transition temperature.

Random Network Model

The random network model depicts glass as a three-dimensional network, lacking symmetry and periodicity, in which no unit of the structure is repeated at regular intervals. For oxide glass, these networks are composed of oxygen polyhedra. Assuming that a glass should have an energy content similar to that of the corresponding crystal, Zachariasen (1932) suggested four rules for the formation of an oxide glass:

- i. An oxygen atom should be linked to not more than two glass forming atoms.
- ii. The coordination number of glass-forming atoms is low, 4 or less.
- iii. Oxygen polyhedra share corners, not edges or faces.
- iv. For 3-D networks, at least three corners of each polyhedron should be shared.

The bonding force responsible for the formation of the network structure in crystalline silica (SiO_2) forms similar networks in glass (see Figure 2(a)) and is considered as network formers. Alkali silicates form glass easily and when alkali oxides such as Na_2O are added to silica glass, the sodium ions become part of the structure and occupy random positions distributed throughout the structure to provide charge neutrality (see Figure 2(b)).

These alkali oxides (e.g., Na_2O , K_2O , Li_2O , CaO , MgO , and PbO) provide additional oxygen ions that modify the network structure. For this reason, they are known as network modifiers. With an increase in the amount of modifiers, the ratio of oxygen to silicon also increases and breaks up the three-dimensional network with the formation of singly-bonded oxygens that do not participate in the network, thus reducing the length of the chain. The principal effect of these modifiers is a reduction in melting temperature and working temperature by decreasing the viscosity. An excess of modifiers can make melting sufficiently simple and mobile that crystallization occurs in preference during the formation of glass. Cations of higher valency and lower coordination number than the alkalis and alkali earth metals may act as both network formers and modifiers and are referred to as intermediates; for example, ZrO_2 , TiO_2 , Al_2O_3 , ZnO .

Amorphous Phase Separation

The phenomenon of amorphous phase separation (APS) in glasses has, for decades now, been an important topic in glass research. It has been the subject of many investigations and there is an entire area of glass science devoted to this phenomenon in different glass-forming systems.

A homogeneous single phase separates into two or more phases of different compositions, if the free energy of the system with two or more distinct phases is lower than that of the system with one single homogeneous phase (Paul, 1990). Phase separation that occurs above the glasses melting point (the liquidus line) is known as stable immiscibility, whereas phase separation at temperatures below the liquidus is known as metastable immiscibility. There are two routes to the formation of discrete phases by metastable phase separation; these are either by spinodal decomposition or by nucleation and growth process. The route taken depends on the free energy of the mixing of the system. Figure 3 shows an immiscibility diagram for the binary sodium silicate system when heat treated in different regions of the phase diagram. The dark phase in the figure represents a sodium rich

Figure 2 Schematic two-dimensional glass structures: (a) amorphous SiO_2 network; (b) SiO_2 network modified through addition of Na_2O .

Figure 3 Metastable immiscibility diagram for the sodium silicate system showing typical morphologies (Wheaton and Clare, 2007).

composition and light phase denotes a silica rich composition. Phase separation in type A and type C (see [Figure 3](#)) are in a binodal region and undergo APS by nucleation and growth process, whereas type B is within the spinodal region and undergoes APS by spinodal decomposition.

Spinodal Decomposition

Because phase separation into the binodal and spinodal regions are achieved by means of different thermodynamic processes, the morphology of the separated phases in each region are distinctly different. Phase separation in the spinodal region refers to a continuous type of phase transformation in which the change begins as small fluctuations in composition, and the compositional differences grow with time resulting in two continuous interpenetrating phases. Since these changes occur spontaneously and as apparently no energy barrier is present to hinder the separation, the region is considered unstable. The system will lower its free energy by continuously changing the composition of two phases until the equilibrium is reached. At this equilibrium, the free energy is in the lowest state and compositions remain constant. Afterwards the phase-separated regions will grow in size through diffusion. The boundary between phases is initially diffuse but sharpens with time. The phases formed in the spinodal region show a high degree of connectivity ([Wheaton and Clare, 2007](#)).

Nucleation and Growth

In the binodal region, a large change in composition must occur to lower the free energy of the system, and thus form nuclei. This region is referred as the metastable region, as the system is unstable to small fluctuations in composition but becomes stable at larger changes in composition. Once nucleated, the new phase will grow in size through diffusion. During the growth stage, the composition of the nucleated phase is unchanged with time, for a constant temperature. The phase separation resulting from nucleation and growth is characterized by spherical droplets, with low connectivity, of random size and distribution with a sharp boundary existing between the two phases. [Figure 4](#) shows etched surfaces of sodium borosilicate glass where the structures are formed by (a) nucleation and growth and (b) spinodal decomposition.

Chemical Durability of Glasses

Chemical durability is a property of a material that is measured by its ability to resist the corrosive action of water, aqueous solution of acids, alkalis and salts. The chemical durability of glasses is superior to most metals and polymers. However, non-silicate glasses are susceptible to dissolution in aqueous solution, especially with low pH solutions. Almost all kind of glasses readily dissolve in hydrofluoric acid (HF) which attacks the network bonds. The glasses, which possess excellent chemical durability, are also attacked significantly if exposed to very high or low pH, – particularly at elevated temperatures.

Chemical Reaction Mechanism

Chemical stability and the resistance of a glass to any chemical attack depend on factors like the solution type, exposure time and temperature, and condition of the glass surface. There are several processes involved during chemical attack by an aqueous solution on glass. However, every chemical attack involves dissociation of water into H^+ or OH^- ions. Ion exchange occurs if the glass contains alkali or other highly mobile ions, where the solution attacks the network bonds to keep the concentration ratio of the components in glass and solution identical. This ion exchange process between highly mobile ions from glass and protonic species from the liquid solution is known as *congruent dissolution* and requires the presence of a liquid or water vapor. Most of the commercial glasses are silicate based glasses that contain alkali ions, and thus their dissolution process usually occurs by congruent

Figure 4 Sodium borosilicate glass showing (a) a droplet microstructure and (b) a connective structure ([Hasanuzzaman et al., 2013, 2014](#)).

dissolution. The reaction products form a layer on the glass surface and influence the further dissolution rate. On the contrary, non-aqueous solutions (i.e., organic) do not react with glass.

At extreme pH (< 1 or > 9), silicate based glasses dissolve at a higher rate where the ion exchange process and leached thin silica gel layer is no longer the determining factor for the dissolution. The chemical attack occurs directly on the Si–O bonds at these extreme pH conditions. For phase separated alkali borosilicate glasses, where two interconnecting phases: a silica-rich phase, and an alkali-rich borate phase formed up on heat-treatment. Leaching is then used on the heat-treated glass to selectively remove alkali borate phase which has very low durability even in weak acids, while silica phase is resistant to this weak acids. A post-leach alkali wash step is needed to remove trapped silica gel and leave behind a silica-rich porous skeleton. The heat-treatment step and leaching conditions can be adjusted to achieve the desired pore size, pore volume, and surface area. Zircon or zirconia can be used to improve the durability of a porous glass (Kiefer, 1989; Marques, 2008; Kiefer, 1989; Okubu *et al.*, 1987; Paul, 1990; Hasanuzzaman *et al.*, 2014).

Crystallization Effect on Chemical Durability

The chemical durability of glasses can be influenced by crystallization if the crystalline phase has properties different to those of the base glass. During crystallization, the mobile ions (i.e., Na^+ or Li^+) of the glass moved in to very durable crystals. In general, the durability of crystalline glass-ceramic is superior to that of amorphous glass. The durability depends on the nature of the crystalline phases formed, the nature of the glassy matrix, and the overall microstructure of the resulting glass-ceramic.

Mechanical and Thermal Properties

Eventhough most glasses possess high hardness values compared to other materials, their brittle nature makes them vulnerable to many engineering applications. Plenty of work has been done to improve the fracture toughness of glass. A number of mechanical and thermal properties of glasses are discussed below which are determining factors for using glass in specific engineering applications.

Viscosity

Viscosity is an important property of glass. Most processing techniques require the viscosity to be in a certain range (10^3 – 10^7 dPa s) at a certain temperature. This is known as the *working point*. At temperature when viscosity of glass reaches $10^{7.6}$ dPa s is defined as the *softening point*. At this point glass, deforms rapidly and is used for glassblowing or sintering. In the glass transformation range (see Figure 1), most glasses show viscosity in the range of 10^{12} – $10^{13.5}$ dPa s, and the upper limit 10^{13} dPa s is called the *annealing point*. Annealing is very important for relaxation of stresses generated during hot forming of glasses (Krause, 2005). At 30–40 °C below the annealing point, where the viscosity is $10^{14.5}$ dPa s, the relaxation of stress requires more time (> 3 h) compare to the annealing point (< 1 h). This is known as the *strain point*. The optimum stress relaxation temperature to use should be chosen according to the application and the requirements of dimensional accuracy.

Below the glass transformation temperature (T_g), the viscosity of glass increases many orders of magnitude and the structure becomes frozen-in (quasi-solid). The rate of cooling influences the density of the glass and also the formation of crystals. In sodium silicate glasses, the most common glass system, increasing the alkali content breaks up the three-dimensional network with the formation of singly-bonded oxygens that do not participate in the network, thus reducing the length of the chain. The principal effect of increased alkali content is to reduce the melting temperature by decreasing the viscosity, which would indicate a lower T_g . However, variations are observed for glass compositions containing B_2O_3 , which is known as the *boric oxide anomaly*. Increasing alkali content in sodium borate glass compositions converts BO_3 triangles to BO_4 tetrahedra, thereby increasing the network connectivity. Therefore, the glass transition temperature increases. Non-bridging oxygen (NBO) sites do not become apparent until the alkali content is increased to approximately 30 mol% (Vogel *et al.*, 1985). In other studies with borosilicate glass, it was mentioned that NBO's are not generated in glasses with a $\text{Na}_2\text{O}/\text{B}_2\text{O}_3$ ratio < 0.5 (Saiki *et al.*, 2010; Chen *et al.*, 2004). Replacement of alkali oxide (Na_2O) by alkaline earth oxide (CaO), while maintaining a constant silica concentration, strengthens the network by replacement of the low field strength sodium ion by the higher field strength divalent alkaline earth ions and thus increases the T_g (Shelby and Lopes, 2005).

Strength

The high theoretical structural strength of glasses (ranges from 1 to 100 GPa), which depends on glass composition, is an attractive property. However, this high strength of glasses cannot be utilized in practical applications due to presence of flaws/defects on its surface which reduce the actual fracture strength by many orders of magnitude. These flaws, in the form of tiny chips or cracks, act as stress concentrators. At the tips of these flaws, stress concentration may be introduced by a load which exceeds the theoretical strength and cause fracture/breakage of the glass. Contact with other hard objects often cause flaws on glass surface. Chemical attacks and thermal stresses introduced during rapid cooling may also generate flaws on glass surface. Annealing can also be a

reason for the reduction of strength as it may introduce small crystals to the glass surface. The thermal expansion mismatch between the matrix glass and these crystals during cooling lead to flaws. In general, it is very challenging to keep glass surfaces free from flaw formation during production process or during annealing. Lubrication or coatings are often applied to the fresh glass surfaces to help prevent the formation of flaws. Reducing the flaw length below the Griffith critical crack length for crack growth, by etching or polishing is another way to improve the glass strength.

Strengthening of glass

As discussed earlier the strength of glasses can be improved by preventing or removing the flaws from the surface which causes the reduction of glass strength. The other way is to prevent the crack growth. Tensile stress concentrates on crack tip while mechanical load is applied to glass and crack propagation occurs when it overcomes the residual compressive stress. Compressive strength of glass which is very high can be exploited for strengthening. Internal stresses can be introduced to the glass by thermal tempering (quenching of softened glass) or ion exchange. By air-quenching glass, compressive stresses can be formed on the surface while the interior is held in tension. In this way, the strength of glass can be increased typically 4–6 times. Such glass is commonly used in bus stops and automobile applications and it has the added advantage that the glass crumbles when broken, as opposed to forming dangerous shards. Ion-exchange or ‘chemical toughening’ works by replacing sodium ions, for example, with potassium ions (which are 30% larger), by immersion of the glass into a bath of molten potassium nitrate. Chemical toughening can be applied to glass objects of complex shapes. Oftentimes, polymeric materials (polycarbonates) are used in combination with glass to form layered composite materials with enhanced properties, as is the case with bullet-proof glass, for example.

Thermal Expansion Behavior

The length and volume of a glass usually increases with increasing temperature. The thermal expansion curve measured by dilatometry gives three important properties – the thermal expansion coefficient (α), glass transformation temperature (T_g), and dilatometric softening temperature (T_d). Coefficient of thermal expansion is a measure of the rate of expansion with temperature. For glasses, the measured expansion coefficient is one directional and measured value is *linear thermal expansion coefficient* (α_l). The linear thermal expansion coefficient value of commercial glasses is measured over a specified temperature range and most cases from 0 to 300 °C, 20 to 300 °C, or 25 to 300 °C (Shelby and Lopes, 2005). Figure 5 shows the linear thermal expansion curve of a bulk sample of an alkali borosilicate glass (Hasanuzzaman *et al.*, 2013). The glass expands until 305 °C, above which the glass contracts suddenly up to about 425 °C, before expanding again. The contraction above 305 °C is believed due to bending of bonds which absorbs the lattice expansion by changing position of atoms. The filling of interstices inhibits further contraction and causes expansion again. Shelby and Lopes (2005) and Kingery *et al.* (1976) revealed a dramatic distinction in thermal expansion behavior between quenched glasses and glasses which had been annealed prior to dilatometric thermal behavior characterization. Quenched glasses showed very prominent contraction–expansion characteristics (see Figure 5). For annealed glasses the expansion–contraction was minimal and to a large extent ‘washed out’ as a result of annealing the glass above T_g . The sudden expansion in the temperature range 430 to 520 °C is referred to as the transformation range and indicates the onset of viscoelastic behavior, where bond breaking is predominant. The onset temperature of the transformation range at 430 °C is attributed to T_g . The temperature of maximum expansion is identified at 550 °C and can be referred to as the dilatometric softening temperature (T_d). A sharp contraction occurs at about 560 °C after the dilatometric softening temperature which corresponds to viscous flow of the sample under stresses imposed by the dilatometric push rod. The linear thermal expansion coefficient of a glass is an essential property for thermally induced stress formation. This property (linear thermal expansion coefficient) is utilized in tempering processes for generating compressive surface layers in order to prevent flaw propagation, hence increasing strength.

Figure 5 Linear thermal expansion curve of alkali borosilicate glass obtained at 10 °C min⁻¹ (Hasanuzzaman *et al.*, 2013).

Electrical Properties

Glasses are well known for their excellent insulating properties. Most oxide glasses are ionic conductor, but very poor electrical conductor due to low numbers of free monovalent ions. Due to its high insulating properties, glasses are used in the area of electrical and electronics engineering for the production of seals, high-voltage insulators, microelectronic packaging, high-vacuum tubes, lamps, etc.

Resistivity

Electrical conductivity in glasses depends on mobility of ions – especially alkali ions. Therefore, the conductivity of the alkali silicate glasses increases with the increasing alkali oxide content. However, for the glasses containing two or more alkali oxides, the *mixed-alkali effect* occurs where the conductivity decreases. Addition of alkaline earth oxide to any alkali containing glass also decreases the electrical conductivity. The immobile divalent alkali earth ions block and occupy the interstitial sites and thus reduce the mobility of the alkali ions in a glass. The conductivity of a glass also very much depend on temperature. At room temperature, the mobility of ions is so small that volume resistivity almost always lies beyond the range of measurement. The ionic mobility increases with increasing temperature and as a result resistivity also decreases. Crystallization also influences the conductivity. If the formed crystal removes alkali ions from the residual glass, the conductivity usually decreases. However, conductivity of the glass-ceramic increases if the crystal phase is free of alkali ions.

Dielectric Properties

The dielectric constant (ϵ_r) of a glass can be described as the relative increase of capacitances by introducing polarizable dielectric into a condenser which is previously separated in vacuum. The dielectric constant of technical glasses usually lies between 4.5 and 8 which is within the range of other electrically insulating material (Krause, 2005). The dielectric constant of glasses primarily depends on the electronic and ionic polarization and increases with temperature. However it decreases very slowly over a wide range of frequency. Content of heavy metals in glass, such as lead and barium containing glasses, gives high values of dielectric constant. If a dielectric material is situated in an alternative electromagnetic field, where reversing the polarities and shifting the dipoles occurs, an inherent dissipation of electromagnetic energy causes heating and the loss quantifies as dielectric loss. The small phase shift (δ) of practical performance to ideal loss free performance is parameterized as *loss tangent* ($\tan \delta$). Dielectric loss commonly depends on relaxation and becomes high around the relaxation or resonance frequencies of the polarization. Dielectric loss in the glasses correlates with its content, frequency, and temperature.

Optical Properties

The optical properties of glasses are of utmost importance and can be subdivided into three categories – refraction, absorption, and transmission of light. Glass is among only few other solids that transmit light in the visible region of the spectrum. Therefore, the development of optical glasses with appropriate refractive index and dispersion characteristics plays an important role in modern scientific evolution, especially in nano-science, medical science, astronomy, and biology.

Refraction of Light

The *refractive index* (n_i) of a material is defined as the ratio of velocity of light in a vacuum to that in a defined material. The refractive index of a glass is not a constant, but depends on the wavelength of the incident light, known as *dispersion*. Dispersion, a decisive factor for optical applications, explains the entire refractive index curve with the wave length of the light over the desired range. Dispersion causes the separation of white or compound light into its constituent colors in prisms, and chromatic aberration in optical lenses. Mean dispersion is the difference between the refractive indices of hydrogen, $n_F - n_C$ ($\lambda_F = 486.1$ nm, $\lambda_C = 656.3$ nm), measured at the F and C emission lines (Shelby and Lopes, 2005; Krause, 2005). For technical glasses, this dispersion value lies between 0.007 and 0.013 (Krause, 2005).

The refractive indices of technical glasses are usually designated as n_D at the yellow emission line of sodium (589.3 nm) or n_d for at yellow emission line of helium (587.6 nm). Due to very close proximity of these wavelengths, there is very little variance of the refractive indices and they generally lie within the range 1.47–1.57. Only exception is for lead based glasses where PbO content is >35% ($n_d = 1.7$) (Krause, 2005; Newton and Davison, 1989).

Effect of composition of glasses on refractive index

Increasing electron density or polarizability also increases the refractive index of a glass. Glasses containing low atomic number ions, which have low electron density and low polarizabilities, also have low refractive indices. Non-bridging oxygens are more polarizable than bridging oxygens. As a result, formation of non-bridging oxygens in a glass system due the compositional change increases the refractive index of that glass and vice versa. For commonly used alkali silicate glasses, refractive indices increases with

increasing alkali oxide concentration. Density and refractive index are directly correlated, such that increasing the density of glass also increases its refractive index.

Absorption

Ultraviolet (UV) light with wavelength (100–400 nm) cannot transmit through glass even if it is transparent. The electrons attached to molecules in typical glasses can absorb radiation at UV wavelengths which are beyond their ultraviolet edge. Conversion of a glass network from bridging state to non-bridging state shifts the ultraviolet edge to lower frequencies and toward the visible region of the spectrum. A very intense absorption band can be achieved in glasses by adding small concentration of impurities (i.e., iron) which result in a very intense absorption band due to transfer of electron from cations to neighboring anions. This absorption band is called *charge transfer band*. Absorption of light in the visible region of spectrum is known as color. Coloring of glass can be created by a number of mechanisms, like (1) addition of either 3d transition metal ions or 4f rare earth (lanthanide) ions, (2) formation or precipitation of colloidal particles, (3) presence of charge transfer bands in the visible region of spectrum, (4) light scattering due to phase separation or other optical defects.

Common Glass Systems

The primary glass formers in commercial oxide glasses are silica (SiO_2), boron oxide (B_2O_3), and phosphorus pentoxide (P_2O_5), all of which readily form single component glasses (Shelby and Lopes, 2005). Of these, other than silica, only boron oxide has some commercial importance and only when mixed with silica. Silica is the most important glass former and silicate glasses represent more than 95% of industrial glass production (Zarzycki, 1991). Silica-based glass is technically important for its excellent chemical resistance (except HF and alkali) and small expansion coefficient which makes it a very good candidate for thermal shock resistance (Zarzycki, 1991). Glass can be classified in different groups according to their intended usage or by their chemical composition. The following sections describe the most common types of glass according to their chemical composition.

Soda-Lime Glass or Commercial Glass

Soda-lime glass is the most common commercial glass. It is comparatively inexpensive and amenable to recycling. A typical composition of this glass is 70–75 wt% SiO_2 , 12–16 wt% of Na_2O , and 10–15 wt% CaO (Bauccio, 1994; Pfaender, 1996). A small percentage of other reagents can be added for specific properties and application requirements. The principal addition in this type of glass, other than silica (SiO_2), is sodium oxide or soda (Na_2O). Even though sodium oxide contains oxygen atoms, it is held together by ionic rather than covalent bonds. The sodium atoms in the mixture donate electrons to the oxygen atom, producing a mixture of negatively charged oxygen ions and positively charged sodium ions. The oxygen atom with an extra electron binds to one silicon atom and does not form a bridge between pairs of silicon atoms. Therefore, the melting temperature of the mixture is considerably reduced (Bloomfield, 2001). Relatively high amount of alkali content in the glass also causes an increase of the thermal expansion coefficient by about 20 times (Pfaender, 1996). Since sodium ions are so soluble in aqueous solution, calcium oxide (CaO) is added to the mixture to improve its insolubility. Soda-lime glass is produced on a large scale and used for bottles, drinking glasses, and windows. Its light transmission properties, as well as low melting temperature, make it suitable for use as window glass. Its smooth and non-reactive surface makes it excellent as containers for food and drinks. Nowadays recycled glass, also known as cullet, is used to make green glass, which helps to save energy and reduce emissions.

Lead Glass

Lead glass is similar to soda-lime glass where lime is replaced by a larger part of lead oxide (PbO). Lead glass typically contains 55–65 wt% SiO_2 , 18–38 wt% of PbO , and 13–15 wt% Na_2O or K_2O (Bauccio, 1994; Pfaender, 1996). Lead glass is usually used for decorative glassware. It is also included in special optical glasses for their high refractive index. The networks in lead glass are more complete than those in soda-lime glass and thus they are stronger and have less internal friction (Bloomfield, 2001). Lead oxide also makes the glass dense, hard, and X-ray absorbing, and therefore suitable for use in radiation shielding.

Aluminosilicate Glass

Aluminosilicate glasses are usually prepared from a ternary system with a typical composition 52–58 wt% SiO_2 , 15–25 wt% of Al_2O_3 , and 4–18 wt% CaO (Bauccio, 1994). With low thermal expansion and high softening temperature, this glass can tolerate high temperature better than soda-lime glass and is used in thermometers, combustion tubes, cookware, halogen lamps, furnaces, and fiberglass insulation.

Borosilicate Glass

Borosilicate glass contains substantial amounts of silica (SiO_2) and boron oxide ($\text{B}_2\text{O}_3 > 8\%$) as glass network formers, and are typically composed of 70–80 wt% SiO_2 , 7–13 wt% of B_2O_3 , 4–8 wt% Na_2O or K_2O , and 2–8 wt% of Al_2O_3 (Bauccio, 1994; Pfaender, 1996). Glass containing 7–13 wt% of B_2O_3 is known as low-borate borosilicate glass, and is mainly used to produce chemical apparatus, lamps, and tube envelopes. Glasses containing 15–25% B_2O_3 , is known as high-borate borosilicate glass. High-borate borosilicate glass is also known as leachable alkali-borosilicate glass with an optimum composition of 62.7 wt% SiO_2 , 26.9 wt% of B_2O_3 , 6.6 wt% Na_2O , and 3.5 wt% of Al_2O_3 (Elmer, 1992). This glass can be further processed to produce Controlled Pore Glass (CPG) which is widely used as a stationary media in chromatography, or alternatively, the pores can be closed up to yield a clear impervious glass known as Vycor 96% silica glass, commonly used in cookware. The increase of B_2O_3 content, coupled with a very fine-scale secondary phase separation within the silica phase increases the chemical resistance, and in this aspect high-borate borosilicate glass differs greatly from low-borate.

Effect of Composition on Glass Properties

The major compounds in borosilicate glass are silicon dioxide and boron trioxide. Alkali metal oxides and alkali earth metal oxides are added up to a certain level in order to optimize the properties. Some other oxides, for example, Al_2O_3 , TiO_2 , ZrO_2 , are added to achieve specific properties depending on end-user requirements. In some cases coloring and refining components are also added.

Silicon Dioxide (SiO_2)

Silicon dioxide is the glass former in borosilicate glass composition. Higher levels of silica increases the melting temperature as well as the working point, and reduces the coefficient of thermal expansion. With lower levels of silica the resistance to acids deteriorates (Peuchert *et al.*, 2004).

Boron trioxide (B_2O_3)

Boron trioxide reduces melting and working temperatures and improves hydrolytic stability when used below 13% by weight in the composition (Reben and Li, 2011). Higher boron trioxide contents have an adverse effect on acid resistance and increases highly volatile alkali metal borates. On the other hand, lower borate contents increase the melting point of the glass by creating secure bonds with alkali metal ions. This helps to reduce the susceptibility to crystallization (Peuchert *et al.*, 2004). Borate also play a major role in reducing the dielectric constant of glass (Reben and Li, 2011).

Alkali Metal Oxides

Sodium oxide (Na_2O) is widely used as a flux, especially in borosilicate glass composition, along with other alkali metal oxides like potassium dioxide (K_2O), lithium dioxide (Li_2O), and lead oxide (PbO). Alkali metal oxide reduces the working temperature and plays an important role in setting the thermal expansion. If the alkali metal oxides content is above a certain limit, glasses exhibit a high coefficient of thermal expansion (Marques, 2008). A higher level of alkali oxide also causes an adverse effect on hydrolytic stability (Peuchert *et al.*, 2004). Peuchert *et al.* (2004) also discussed the role of alkali metal oxides on crystallization and suggested using at least two alkali metal oxides, even in small amounts, in order to have a positive effect on resisting unwanted crystallization. They also reported that beyond 1000 °C, potassium borates evaporate more easily than sodium borates, while lithium borates are, by comparison, more stable in terms of evaporating when the glass is heated (Shelby and Lopes, 2005). Li^+ forms strong bonds with the glass network and increases the acid resistance of the glass (Marques, 2008). The use of PbO , which is an excellent flux, is becoming limited these days due to concerns regarding lead toxicity.

Alkali Earth Metal Oxides

Calcium oxide (CaO) is most commonly used as a property modifier component in glass composition. Small amounts of magnesium oxide (MgO), zinc oxide (ZnO), strontium oxide (SrO), and barium oxide (BaO) are also added separately based on application requirements. Calcium oxide can help greatly to accelerate the phase separation of borosilicate glasses (Eguchi *et al.*, 1988; Kokubu *et al.*, 1987; Yazawa *et al.*, 1994). It also has a stabilizing effect on acid resistance (Watzke *et al.*, 1998). It has been found that limiting CaO to small amounts reduces the evaporation of highly volatile sodium and potassium borate compounds during hot forming (Peuchert *et al.*, 2004). If the amount of CaO exceeds certain limit, devitrification is likely to take place. Moreover, heat resistance and alkali resistance also deteriorate with high contents of CaO (Kokubu *et al.*, 1987). Eguchi *et al.* (1988) has proposed using ZnO to promote ZrO_2 retention in the SiO_2 rich phase at a time of phase separation, thereby maximizing ZrO_2 content in the porous silica-rich skeleton for enhanced alkali-durability.

Other Property Modifying Oxides

Zirconium dioxide (ZrO_2), aluminum trioxide (Al_2O_3), and titanium dioxide (TiO_2) are other commonly used property-modifying oxides. It has been shown that ZrO_2 greatly improves the alkali resistance of borosilicate glass without the glass suffering in terms of the hydrolytic stability and resistance to acids (Kiefer, 1989; Marques, 2008; Kiefer, 1989; Kokubu *et al.*, 1987; Paul, 1990). However, higher ZrO_2 contents increase the working point as well as the risk of flaws forming in the glass. With excessively high ZrO_2 contents, crystallization is likely to occur (Eguchi *et al.*, 1988). Although small amounts of ZrO_2 suppress devitrification, they reduce the growth rate of phase separation due to an increase of glass viscosity (Kukizaki, 2010). There is also a risk of passing un-melted ZrO_2 into the product (Peuchert *et al.*, 2004). Kord *et al.* (2009) claim that addition of ZrO_2 (6 mol%) almost doubled the bending strength. Alumina, most commonly used as a modifying oxide (Eguchi *et al.*, 1988), has mixed effect on the property of the borosilicate glass. It increases insolubility as well as resistance to devitrification of the borosilicate glass, while inhibiting phase separation (Marques, 2008; Rose *et al.*, 2011; Doremus, 1994). Fluidity of the glass decreases with the addition of Al_2O_3 in these glass compositions (Marques, 2008). Alumina also acts as a balancing component to allow relatively high levels of CaO in the borosilicate system. Alumina also acts to prevent cracks during leaching (porous glass production) and improve moldability by minimizing the viscosity change relative to the change in temperature (Kokubu *et al.*, 1987). Titania is used in small quantities for special applications where UV absorption is required (Peuchert *et al.*, 2004; Shorrocks and Yale, 1993). It is also believed that the presence of TiO_2 suppresses crystallization (Mojumdar, 2004).

Refining Component

Borosilicate glasses can be refined with small amounts ($\leq 1\%$ by weight) of conventional refining agents, such as chlorides, for example, NaCl, and sulphates, Na_2SO_4 or BaSO_4 , fluorides, and bromides. Amongst other refining agents CeO_2 , As_2O_3 , Sb_2O_3 , and CaF are noteworthy (Yazawa *et al.*, 1999; Peuchert *et al.*, 2004). These refining components are also used to remove undesirable color tinges.

Coloring Components

Fe_2O_3 , Cr_2O_3 , and CoO are the most commonly used coloring components in glasses. Oxides of other transition elements (copper, manganese, nickel, vanadium, titanium) and rare earths (mainly neodymium and praseodymium) are also used to obtain different colored glasses, usually $< 3 \text{ wt}\%$ (Pfaender, 1996).

Optical Glass: Challenges From Optical Design

Ulrich Fotheringham, Martin Letz, Uwe Petzold, Simone Ritter, and Yvonne Menke-Berg, Schott AG, Mainz, Germany

© 2021 Elsevier Inc. All rights reserved.

Introduction

Current technological trends such as augmented reality, automotive assistance systems, laser technology and three-dimensional printing would not be possible without modern photonics (Petzold, 2018). Such systems have been made possible through a revolution in the field of optics over the last 50 years and – simultaneously – of the materials used within.

Optical design started to trigger the development of novel optical materials about 400 years ago, with the invention of the first microscopes and telescopes in the 17th century (Hartmann, 2014). However, even by the end of the 19th century the manufacturing methods for such optical instruments were still unsatisfying. This was the starting point for Carl Zeiss who ran a manufactory of optical instruments at Jena University to team up with optics expert Ernst Abbe to design high quality microscopes. They identified the need for novel glass types with – compared to what was common at that time – essentially different dispersion properties.

At the same time the glass chemist Otto Schott was making experimental glass melts which he sent to Abbe and which were found to meet exactly the need defined by Abbe and Zeiss (Petzold, 2018; Hartmann, 2014; Hartmann *et al.*, 2010). Thus modern optical glass chemistry was born (Bach and Neuroth, 1998).

The outline of optical glasses given here follows the red thread provided by the interplay of progressing optical design, arising needs for novel optical materials and the corresponding invention of special optical glasses. The starting point is the basic electrodynamics of light and its interaction with matter.

Basic Electrodynamics

Electromagnetic Waves and Their Interaction With Matter

The basic physics of electrodynamics (Jackson, 1999), including the interaction with matter, is described by Maxwell's equations:

$$\begin{aligned}\nabla \cdot \mathbf{D} &= \rho \\ \nabla \cdot \mathbf{B} &= 0 \\ \nabla \times \mathbf{E} &= -\dot{\mathbf{B}} \\ \nabla \times \mathbf{H} &= \mathbf{j} + \dot{\mathbf{D}}\end{aligned}\quad (1)$$

$\mathbf{E}$ and $\mathbf{H}$ denote the electric and the magnetic field. $\mathbf{B}$ is the magnetic flux density, $\mathbf{D}$ is the dielectric displacement. In (1) and throughout this text, bold letters symbolize vector quantities. The dot denotes the time derivative. ρ and $\mathbf{j}$ stand for charge and current density, respectively. Material equations are needed to close Maxwell's equations:

$$\begin{aligned}\mathbf{D} &= \varepsilon \cdot \varepsilon_0 \cdot \mathbf{E} = (1 + \chi_E) \cdot \varepsilon_0 \cdot \mathbf{E} \\ \mathbf{B} &= \mu \cdot \mu_0 \cdot \mathbf{H} = (1 + \chi_M) \cdot \mu_0 \cdot \mathbf{H}\end{aligned}\quad (2)$$

ε_0 is the vacuum permittivity (in SI units) and amounts to $\varepsilon_0 = 8.854 \times 10^{-12}$ As/(Vm). ε is the relative permittivity and is a material property. χ_E is called electric susceptibility. μ_0 is the vacuum permeability and amounts to $\mu_0 = 4\pi \times 10^{-7}$ Vs/(Am). μ is the relative permeability and is a material property. χ_M is called magnetic susceptibility. For conventional optical materials one finds $\chi_E > 0$, $\chi_M = 0$. In general ε and μ are second rank tensor quantities. In homogeneous isotrop media, like glasses, they can be replaced by a scalar quantity, which we do in the following.

The complete optical properties for any spatial combination of matter are included in the solution of Eqs. (1) and (2) and by using appropriate boundary conditions. In the absence of mobile charges and currents, the solutions of Eqs. (1) and (2) are undamped electromagnetic waves.

Wave Propagation in Vacuum

In infinite vacuum, Eqs. (1) and (2) can be solved (Jackson, 1999) using the following boundary conditions and material equations:

$$\varepsilon = 1, \mu = 1, \rho(\mathbf{r}) = 0, \mathbf{j}(\mathbf{r}) = 0 \quad (3)$$

with $\mathbf{r} = (x, y, z)$ being the vector representing the position in space. After applying a few vector operations, a wave equation for the electric field $\mathbf{E}$ in vacuum is obtained:

$$\Delta \mathbf{E} - \varepsilon_0 \mu_0 \ddot{\mathbf{E}} \quad (4)$$

Once Eq. (4) has been solved, the magnetic field can be calculated from Maxwell's equations.

Any solution of Eq. (4) can be represented by an integral over a set of fundamental solutions, for instance, polarized planar waves:

$$E = \iiint_{\mathbf{k}} \left(v_1(\mathbf{k}) \mathbf{e}_1(\mathbf{k}) e^{i(\mathbf{k}\mathbf{r} - \omega t)} + v_2(\mathbf{k}) \mathbf{e}_2(\mathbf{k}) e^{i(\mathbf{k}\mathbf{r} - \omega t)} \right) \quad (5)$$

$\mathbf{k}$ is the wave vector which indicates the direction in which each individual plane wave $v_{1,2}(\mathbf{k}) \mathbf{e}_{1,2}(\mathbf{k}) e^{i(\mathbf{k}\mathbf{r} - \omega t)}$ propagates. ω is the corresponding angular frequency. From inserting Eq. (5) in Eq. (4) it follows that ω must fulfill the condition $\omega = c \cdot k$ with c given by:

$$c^2 = \frac{\omega^2}{k^2} = \frac{1}{\varepsilon_0 \mu_0} \quad (6)$$

c is the vacuum velocity of electromagnetic waves, in particular of light. k^2 denotes the scalar product $\mathbf{k} \cdot \mathbf{k}$.

The corresponding wavelength λ follows from $\lambda = 2\pi/k$ with $\mathbf{k} = |\mathbf{k}| \cdot \mathbf{e}_1(\mathbf{k})$ and $\mathbf{e}_2(\mathbf{k})$ are unit vectors which are orthogonal to $\mathbf{k}$ and to each other (electromagnetic waves are transversal waves). $v_1(\mathbf{k})$ and $v_2(\mathbf{k})$ are the corresponding amplitudes the magnitude of which is determined by the boundary conditions.

Wave Propagation in an Ideal Transparent Refracting Medium

In the case when all geometric dimensions are much larger than the wavelength of the light, the propagation of these electromagnetic waves can be described as light rays. A ray is propagating in the direction of the corresponding $\mathbf{k}$ vector. As demonstrated by Fig. 1 for a lens shaped material in vacuum, this ray will change its direction at the interface between vacuum (or air) and a solid material such as glass, i.e., it will be refracted (Petzold, 2018). The size of this effect is given by Snell's law (Perret-Optic, 2005):

$$\frac{\sin(\alpha + \gamma)}{\sin(\gamma)} = n \quad (7)$$

n is a material constant, the so-called refractive index.

Within the formalism of electrodynamics, this effect is described by applying the value $\varepsilon = n^2$ for the relative permittivity in the glass. With this, the corresponding boundary conditions at the interface will lead to the direction change of $\mathbf{k}$ observed. For the wave function in the glass, $\varepsilon = n^2$ means:

$$E = \iiint_{\mathbf{k}} \left(v_1(\mathbf{k}) \mathbf{e}_1(\mathbf{k}) e^{i(n\mathbf{k}\mathbf{r} - \omega t)} + v_2(\mathbf{k}) \mathbf{e}_2(\mathbf{k}) e^{i(n\mathbf{k}\mathbf{r} - \omega t)} \right) \quad (8)$$

So the velocity of light in the glass is c/n rather than just c .

As Fig. 1 (redrawn from Perret-optics, 2005) also demonstrates, n is not a constant but dependent on the wavelength or frequency: $n = n(\lambda_0) = n(\omega)$. Note that λ_0 denotes the vacuum wavelength. In the glass, λ is given by $\lambda = \lambda_0/n$ which is consistent with the relationship between wavelength and angular frequency in a material with refractive index n , i.e., $\lambda \cdot \omega/2\pi = c/n$.

In most cases and if it is not stated otherwise, n refers to the vacuum wavelength of the "d" absorption line at 587.49 nm which is caused by Helium and which has first been observed in the solar spectrum. This can be indicated by writing " n_d " (Bach and Neuroth, 1998).

The dispersion of the different wavelengths after refraction is definitely a challenge both for optical design and optical material development. For perfect optical imaging, it should be zero.

Fig. 1 Significance of Refractive index and Abbe number. Modified and redrawn from Perret-Optic, 2005. Available at: www.perret-optic.ch/optometrie/correction_optique/matiere_optique_qualite_%20physique/matiere_optique_qualite_phys_gb.htm. (downloaded on 02/09/2005).

With respect to the importance of this issue, Ernst Abbe ([Bach and Neuroth, 1998](#)) introduced a dimensionless number to characterize the dispersion of an optical material. Its significance is also demonstrated in [Fig. 1](#). It is equal to α/δ , i.e., the proportion of the refraction angle α of a wavelength in the center of the visible spectrum (587.49 nm, see above) and the angle δ indicating the difference of the refraction angles of the blue and the red fringe of the visible spectrum. “blue” is represented by the Hydrogen F absorption line (486.12 nm), “red” is represented by the Hydrogen CF line (656.27 nm).

The following consideration leads to a relationship between α/δ and the refractive indices at the three wavelengths 486.12 nm, 587.49 nm, and 656.27 nm. With $\sin(\varphi) = \varphi$ for any small angle φ one obtains $1 + \alpha = n_d$. Applying this relationship on the red and the blue ray as well, one finally obtains Abbe's classical definition:

$$v_d = \frac{n_d - 1}{n_F - n_C} \equiv \frac{\alpha}{\delta} \quad (9a)$$

In the new definition, “green” is represented by the Mercury e line (546.074 nm), “blue” is represented by the Cadmium F' line (479.99 nm), “red” is represented by the Cadmium C' line (643.8469 nm).

$$v_e = \frac{n_e - 1}{n_{F'} - n_{C'}} \quad (9b)$$

The new definition had become necessary because the classical definition of the Abbe number refers to the three colors red, yellow, and blue whereas today's color generation usually starts at red, green, and blue (RGB) as basic color set.

Wave Propagation in a Weakly Absorbing Medium

Weak absorbance can be taken into account by the planar wave formalism if one introduces a complex refractive index ([Jackson, 1999](#)).

With

$$n^* = n + i \cdot n_i \quad (10)$$

and

$$\kappa := 2 \cdot i \cdot n_i \cdot k \quad (11)$$

one obtains for any plane wave $E_{k,\omega}$ with wave vector $\mathbf{k}$ and angular frequency ω :

$$E_{k,\omega} = v_{1,2}(\mathbf{k}) e_{1,2}(\mathbf{k}) e^{i(n\mathbf{k}\cdot\mathbf{r} - \omega t) - \frac{\kappa\cdot\mathbf{r}}{2}} \quad (12)$$

This means that the plane wave is attenuated in the direction of its propagation. The intensity E^2 exponentially decreases with $\kappa \cdot \mathbf{r}$ so that $|\kappa| = 2 \cdot i \cdot n_i \cdot 2\pi/\lambda$ is equal to the absorption coefficient.

Close to the absorption edge in the UV spectral range, materials, in most cases, show strong absorptions, optical materials become non-transparent and leave the assumption of being weakly absorbing media (see [Fig. 9](#)).

Optical Glass: Challenges From Optical Design

The Abbe Diagram

A good starting point for understanding the systematics of optical glass is the Abbe Diagram where optical glasses are sorted according to their refractive indices and Abbe numbers. This order system reflects the necessities of optical design which in return have triggered the developments of optical glasses in the last centuries.

[Fig. 2](#) shows the Abbe Diagram according to both its classical and the new definition ([schott.com, 2019](#)).

The acronyms of the various glass types are listed in [Table 1](#):

In the following section, the significance of the glasses in the different parts of the Abbe diagram are explained. It will also be explained why the upper left of the Abbe diagram is empty (and will always be).

Challenge From Conventional Lens Making: High n to Suppress Spherical Aberration

To understand the necessities from optical design, one has to consider the technologies for manufacturing optical components as they had dominated until the late 20th century.

Lens making, in particular grinding and polishing, can easily be carried out by a set-up of rotating devices ([Hartmann, 2014](#)), see [Fig. 3](#) (redrawn from [Schwertz, 2008](#)). The polishing or grinding device oscillates around the center of curvature of the lens element to be polished. Both the polishing device and the lens support rotate around their axes. The sketch shows the polishing of a convex lens element. There is, however, also an equivalent setup for concave lens elements.

The disadvantage of such a machine is that it can only produce spherical spheres. Spherical surfaces, however, cause spherical aberration, see [Fig. 4](#).

Spherical aberration is an issue that primarily affects rays far off the optical axis. To assess the effect for a lens element such as the one in [Fig. 4](#) and to find a way to suppress it, it is necessary to start with Snell's law:

Fig. 2 Abbe diagram (a) According to classical definition; (b) According to the new definition. Reproduced from Schott.com, 2019. Table 1 Significance of the acronyms for glass types

FK	Fluorite crown
PK	Phosphate crown
PSK	Dense phosphate crown
BK	Borosilicate crown
BAK	Barium crown
SK	Dense crown
K	Crown
LAK	Lanthanum crown
SSK	Very dense crown
BALF	Barium light flint
KF	Crown/flint
LASF	Lanthanum dense flint
LAF	Lanthanum flint
BAF	Barium flint
BASF	Barium dense flint
LF	Light flint
LLF	Very light flint
F	Flint
SF	Dense flint
ZK	Zinc crown
KZSF	Special short flint

**Fig. 3** Conventional lens making. Redrawn from Schwartz, K., 2008. An Introduction to the Optics Manufacturing Process. University of Arizona, College of Optical Sciences. (OPTI 521 report).

$$n \cdot \sin(\alpha) = \sin(\beta) = \sin(\alpha + \gamma) \quad (13)$$

and the following geometrical relationship between the radius of curvature R of the spherical surface of the lens element, the distance h between the incoming ray and the optical axis, the angles α , γ and the focal length f , i.e., the position where the ray under consideration crosses the optical axis:

$$R \cdot \sin(\alpha) = h = (R - R \cdot \cos(\alpha) + f) \cdot \tan(\gamma) \quad (14)$$

For small values of h and α , one may apply 1st order Taylor which gives $\sin(\alpha) \approx \alpha$, $\sin(\alpha + \gamma) \approx \alpha + \gamma$, $\cos(\alpha) \approx 1$, $\tan(\gamma) \approx \gamma$. With this, Snell' law becomes $n \cdot \alpha = \alpha + \gamma$, the geometrical relationship becomes $R \cdot \alpha = f \cdot \gamma$. This means for f :

$$f = \frac{R}{n - 1} \quad (15)$$

Fig. 4 Spherical aberration.

So for small values of h and α , the focal length is independent of h , i.e., there is no longitudinal spherical aberration.

For bigger values of h and α , a 2nd order Taylor approximation has to be applied which means $\cos(\alpha) \approx 1 - \alpha^2/2$ in particular. This means for f :

$$f = \frac{R}{n-1} - R \cdot \frac{\alpha^2}{2} = \frac{R}{n-1} - \frac{h^2}{2R} \quad (16)$$

So for bigger values of h and α , the focal length depends on h via $h^2/(2R)$, i.e., there is longitudinal spherical aberration. To minimize $h^2/(2R)$, R must be as large as possible. To prevent a change of the focal length of the rays close to the optical axis, this increase of R has to be compensated by a corresponding increase of n .

This fact has directed optical glass development over more than 200 years! One major drive to develop glasses with high refractive indices has been the need to suppress spherical aberration.

How to Make Glasses With High Refractive Index n

Through the Clausius-Mosotti equation (Kittel, 2018) for the wavelength range of visible light (Lorentz-Lorenz equation), the refractive index – a macroscopic quantity – in said wavelength range can be related to the atomic polarizability – a microscopic quantity:

$$\frac{n^2 - 1}{n^2 + 2} \equiv \frac{\chi_E}{\chi_E + 3} = \frac{\rho}{M} \frac{1}{3\epsilon_0} \sum_j N_j \alpha_j \quad (17)$$

ρ is the density, M the molar mass of the glass, N_j the number of atoms of the j -th type of element/mole, and α_j is the corresponding electronic polarizability. It characterizes the linear electronic response of an atom to an imposed electric field. By said electric field, an electric dipole μ is induced which size is described as follows:

$$\mu = \alpha \cdot E_{\text{local}} \quad (18)$$

Note that Eq. (18) refers to the local electric field whereas (2) refers to the global electric field. The difference between both of these is explained in the textbooks such as (Jackson, 1975) where the derivation of Eq. (17) is given. It is this difference between local and global electric field which is responsible for the rather complicated expressions in Eq. (17).

Considering Eq. (17), one finds that dense packing and high electronic polarizabilities of the atoms involved are necessary to obtain high refractive indices.

A rough analysis gives a hint of how high electronic polarizabilities can be achieved (Hartmann et al., 2010). Considering a spherical atom or ion with a homogeneous electronic charge density, the dipole μ induced by the local electric field E_{local} is:

$$\mu = ze \cdot d_E = 4\pi\epsilon_0 \cdot R^3 \cdot E_{\text{local}} \quad (19)$$

z is the number of electrons and e is the elementary charge. See Fig. 5 (redrawn from Föll, 2019) for the significance of d_E . Eq. (19) is derived by the following consideration:

The force exerted on the nucleus by E_{local} is given by the product of its charge $+ze$ and E_{local} . The balancing force from the electron cloud is given by Coulomb's law. Note that for the latter, only the part of the electronic charge at radii $r < |d_E|$ counts (a sphere charged on the outside has no field in the inside, and therefore no force), i.e., $-ze \cdot |d_E|^3/R^3$. One obtains Eq. (20) from which Eq. (19) follows by fraction reduction:

$$\frac{(ze) \cdot \left(-ze \cdot \frac{|d_E|^3}{R^3} \right) d_E}{4\pi\epsilon_0 \cdot |d_E|^2} + ze \cdot E_{\text{local}} = 0 \quad (20)$$

Fig. 5 Atom Size and Polarizability. Redrawn from Föll, H., 2019. Electronic Materials. University of Kiel. Available at: www.tf.uni-kiel.de/matwis/amat/elmat_en/kap_3/backbone/r3_2_2.html. (Downloaded 17.06.2019).

Comparing Eqs. (18) and (19) the polarizability per atom follows as:

$$\alpha = 4\pi\epsilon_0 \cdot R^3 \quad (21)$$

Although the assumption of spherical atoms or ions is not always justified, the general tendency is true that the electronic polarizability scales with the size of the atoms or ions. So large atoms are required.

For oxide glasses most of the electronic polarizability comes from the oxygen anion, which is larger than most cations, as found in the periodic system. In order to obtain very high refractive indices oxygen is usually combined with cations, which have the same size or are even larger than the oxygen anion. Such cations are found in the lower left corner of the periodic system, see Fig. 6, which provides the effective ion radii (Shannon and Prewitt, 1969; Bach and Neuroth, 1998) for all cations that are important for glass making, the bandgaps of the corresponding oxides (Portier *et al.*, 2001; Gillen and Robertson, 2013; Ma *et al.*, 2017; Islam *et al.*, 2012; Quah and Cheong, 2015; Ziletti *et al.*, 2015; Robertson, 2004; Hsu *et al.*, 2013; Guo *et al.*, 2018; Abul-Hail *et al.*, 2012; Mansoob Khan *et al.*, 2014) and Dietzel's field strength for all cations commonly used in glassmaking (Dietzel, 1942).

Note that cation radii depend on charge and coordination number; for the periodic table, the charges and coordination numbers of the cations in the most stable/common simple oxides have been selected. The ionic radius of the oxygen ion is 1.4 Å in six-fold coordination. It does not depend strongly on the coordination number, however, so that 1.4 Å may be taken as a universal value.

Therefore, the large ions pave the path for the development of higher refractive index glasses which enable the correction of spherical aberration, i.e., by moving to higher values along the vertical axis of the Abbe diagram (Shannon and Prewitt, 1969; Jackson, 1999; Portier *et al.*, 2001; Schwartz, 2008; Islam *et al.*, 2012; Gillen and Robertson, 2013; Ma *et al.*, 2017; Kittel, 2018; Föll, 2019).

The second essential task of optical imaging is to suppress chromatic aberration. In contrast to spherical aberration, it is not caused by shortcomings of the manufacturing process but by the dispersion, i.e., the frequency dependence, of the electronic polarizability, which is an essential feature of the latter.

Challenge From an Intrinsic Material Property: Dispersion

The electronic polarizability describes the material response to an electric field imposed from outside. In optics, this field is oscillating at high frequencies (10^{14} – 10^{15} Hz). By nature, optical glasses are transparent in this frequency range. Note that transparency of a solid material, which has been known to mankind for several thousand years, can only be understood by taking into account the quantum mechanics concept of electronic bands (see Figs. 9 and 10). There is a high frequency absorption edge, however, which does not only limit transmission in the UV but also gives rise to the observed dispersion, i.e., the frequency or wavelength dependence of the electronic polarizability.

The essential features can be illustrated considering a mechanical analog, the spring pendulum, Fig. 7.

With the angular frequency ω of the exciting force $f = f_0 \cdot \cos(\omega t)$ approaching the angular eigenfrequency ω_0 from below, one observes a super-linearly increasing response $x = x_0 \cdot \cos(\omega t)$, i.e., an increase of the dispersion.

Fig. 7 Mechanical Analog of a two-cation molecule.

Fig. 8 Frequency dependence of the response to an external force or electric field.

Fig. 9 Lower limit for the bandgap of oxides entering an optical glass. Redrawn from Energyeducation.ca, 2019. Available at: https://energyeducation.ca/encyclopedia/Band_gap. (Downloaded on 17.06.2019).

Fig. 10 Comparison of (a) Transmission and (b) Refractive Index variation dependent upon Wavelength.

How to Make Glasses With Low Dispersion

As has been said, the material selection for low-dispersion glasses should be such that oxides with small bandgaps should be avoided, in particular oxides with a bandgap smaller than 3.1 eV, which corresponds to an absorption edge at the low wavelength borderline of the visible window, i.e., 400 nm, see again Fig. 6.

Comparing the requirements resulting from the demand for high indices and low dispersion, some antagonism between these two goals exists. The cations belonging to the oxides with high bandgaps are in the upper right corner of the periodic system, not in the lower left one where the cations particularly suited for a high refractive index are found. Considering Fig. 6, however, there are some oxides which meet both requirements – among them BaO, a classical component of high index, low dispersion glasses.

Unfortunately, the stated antagonism is not a unique feature of optical glasses but the consequence of a universal law, the so-called Kramers-Kronig relations (Kittel, 2018) which state that within linear response theory, there is an interrelation between the real part and the imaginary part for any susceptibility, in particular for the electric susceptibility, independent from the material (glass or polymer or ...):

$$\varepsilon(\omega) = 1 + \chi = 1 + \chi_r(\omega) + i\chi_i(\omega) \quad (23)$$

$$\chi_r(\omega) = \frac{2}{\pi} \cdot P \int_0^{\infty} \frac{\omega' \cdot \chi_i(\omega')}{\omega'^2 - \omega^2} \cdot d\omega' \quad (24)$$

P: Cauchy's principal value of the integral.

With $\varepsilon = n^2 = (n + i \cdot n_i)^2 = n^2 + 2 \cdot i \cdot n \cdot n_i = n^2 + n \cdot |k| \cdot \lambda / 2\pi$, $\kappa = |k|$, one gets:

$$n^2(\omega) = 1 + \frac{2c}{\pi} \cdot P \int_0^{\infty} \frac{n(\omega') \kappa(\omega')}{\omega'^2 - \omega^2} \cdot d\omega' \quad (25)$$

The message conveyed by Eq. (25) is that in any material there is no high refractive index without an absorbance issue (consider the numerator of Eq. (25); there has to be a non-zero k in the vicinity of ω on the frequency scale) and a dispersion issue (consider the denominator of Eq. (25)).

This is what makes optical material development a challenge. It also explains why the upper left corner of the Abbe diagram is empty and will be forever.

In addition to this general finding, the Kramers-Kronig rules have a practical application.

A crude but very practical simplification of Eq. (25) is the Sellmeier series. It approximates the complete dispersion of a transparent material by three sharp absorption lines; two lines in the UV part of the electromagnetic spectrum and one in the infrared part with coefficients B_i , C_i . Note that the coefficients B_i are unitless and the coefficients C_i are usually given in μm^2 and λ is given in μm . The coefficients have to be provided for each glass (and will be available in any comprehensive optical glass catalog):

$$n(\lambda) = \left(1 + \frac{B_1}{1 - \frac{C_1}{\lambda^2}} + \frac{B_2}{1 - \frac{C_2}{\lambda^2}} + \frac{B_3}{1 - \frac{C_3}{\lambda^2}} \right)^{\frac{1}{2}} \quad (26)$$

Challenge From Glass Making

With what has been said so far, glasses only consisting of components such as BaO would be perfectly suited as optical materials. Such compositions, however, do not fit to the rules of glassmaking. A glass forming composition must have a certain amount (rule of thumb: > 50 mol%) of glass formers, i.e., oxides with strong covalent bonds. One may identify suitable oxides

by considering field strength (see Dietzel, 1942) of the corresponding cations, see again Fig. 6. For oxides, Dietzel's field strength F is defined as:

$$F = \frac{z_c}{(r_c + r_o)^2} \quad (27)$$

z_c is the charge of the cation, r_c is the radius of the cation, and r_o is the radius of an oxygen ion.

The higher the latter, the more suited the corresponding oxides are for glassmaking. This is why silicon dioxide, germanium dioxide, boron trioxide and phosphorus pentoxide are called (glass) network formers whereas other oxides are classed as network modifiers or intermediates, depending on the field strength (Dietzel, 1942).

For optical glasses, usually one or more of these network formers is combined with, e.g., barium oxide BaO (see above). With respect to the combination of a high-enough bandgap material, a not-so-small cation radius, and also not-so-small value of Dietzel's cation field strength, one other prominent network modifier oxide to be combined with network formers is lanthanum oxide La_2O_3 .

With respect to the inclusion of barium oxide and lanthanum oxide within the compositions of optical glasses, a number of optical glass types bear their names, see Table 1. However, numerous other network modifier oxides are used in optical glasses, e.g., to optimize the packing density which is another criterion for high polarizability, see the Clausius-Mosotti Eq. (17) above.

To a certain extent, intermediate oxides such as niobium pentoxide, bismuth oxide or tellurium dioxide may substitute for network formers. This gives rise to niobium phosphate, bismuth, and tellurite glasses.

Transmission

The interdependence between refractive index, dispersion, and absorption suggests that, beside the optical position in the Abbe diagram, transmission is the third critical property of optical glass.

The intrinsic property involved is called pure transmission. It gives the exponential attenuation $e^{-\kappa \cdot d}$ of the electromagnetic radiation in a sample and can be determined from its transmission by correction for the reflection losses at both sides.

The transmission T of an absorbing plate of thickness d is given by Soler (1997):

$$T = \frac{(1 - \rho)^2 e^{-\kappa \cdot d}}{1 - \rho^2 e^{-2 \cdot \kappa \cdot d}} \quad (28)$$

ρ is the reflection at the surface. For perpendicularly incident light, ρ is given by:

$$\rho = \frac{(1 - n)^2}{(1 + n)^2} \quad (29)$$

With (28) and (29), the pure transmission can be calculated from measured transmission data, see Fig. 9.

Oxides used for optical glassmaking are selected with respect to their transparency in the visible range, which always means the near infrared also. There is, however, a low wavelength boundary of the transmission window. This UV absorption edge may come close to the visible range by design if a high dispersion or low Abbe number is required by the application, see Fig. 9 and below.

Roughly speaking, the UV absorption edge marks the bandgap of the glass, which in return is determined by the bandgaps of the oxides involved. Analyzing the glass structure one finds that the position of the UV absorption edge depends on the quotient of the number of bridging oxygens and the number of network former cations. The larger this quotient, the further this edge is in the UV.

The quotient will be a maximum in a glass consisting of network formers only. In vitreous silica (glass made from high-bandgap SiO_2), for instance, this quotient is "2" since all oxygen atoms are building a bridge from one silicon atom to another. If one adds modifiers like low-bandgap Na_2O , some of these bridges are destroyed. In $\text{Na}_2\text{O-SiO}_2$ glass, the said quotient is "1". Simultaneously to adding Na_2O to SiO_2 glass, the UV edge will move to longer wavelengths.

As it is clear from the above, moving the UV edge to longer wavelengths will increase the refractive index (usually wanted) and the dispersion (usually unwanted, but there are exceptions). However, this is not the only possible reason for an absorption edge close to the visible range. UV blocking may be another motive. This can be achieved by TiO_2 or CeO_2 doping (see the bandgaps of these oxides in Fig. 6). This doping will also protect the glass from damage caused by UV (solarization).

Optical Glass Families

With what has been said so far, it is expected that glass families suited for high index and/or low dispersion should be combinations of borates, silicates and heavy ion oxides (Bach and Neuroth, 1998). Indeed, this is the case, see Fig. 11 (Bach and Neuroth, 1998).

Remarkably, the two cations which have been identified as particularly attractive for optical glasses above by theoretical considerations, i.e., Barium and Lanthanum, really play a prominent role. Barium- and Lanthanum containing glasses like N-LAK8 with low dispersion and high index can be found in the top center of the Abbe diagram.

In the bottom center, there are glasses like Schott N-BK7® with low dispersion and moderate refractive index for regular optics. In the bottom left, there are ultralow dispersion phosphate glasses for high-end optics. No glasses can be found in the top left because of the Kramers-Kronig relations.

The special role of high dispersion glasses like N-SF6 situated in the top right position of the Abbe diagram is discussed below.

Fig. 11 Families of optical glasses (see Bach, H., Neuroth, N. (Eds.), 1998. *The Properties of Optical Glass*, Schott Series on Glass and Glass Ceramics, second ed. Berlin, Heidelberg, New York: Springer).

Note that in most formerly lead oxide-containing glasses, PbO has now been substituted. For some of them, for instance SF6, both the classical and the arsenic- and lead-free N-type glass are available.

Meeting the Above Challenges by Glass Selection and Multi-Lens-Element Optical Design

With a glass like N-LAK8, a single lens element combining low spherical and chromatic aberration can be manufactured (Fig. 12(a); note that the primary color issue is intentionally exaggerated). For most applications, however, this is not enough: it is desirable to make certain aberrations to be almost or exactly zero.

These tasks can only be fulfilled with a multiple lens element set-up. Splitting up the refractive power of an optical system among various lens elements significantly reduces spherical aberration; combining lens positive and negative elements with very much different Abbe numbers enables color correction.

Primary Axial Color Correction by a Two Element Lens System: Achromatic Lens

A two-lens element system where the “red focus” and the “blue focus” are at the same point is called achromatic lens, see Fig. 12(b). Such a complete suppression of primary axial color is possible by combining a positive element with a high Abbe-number and a negative element with a low Abbe-number (Fischer *et al.*, 2008).

To find a suitable combination of refractive indices and Abbe numbers, some calculations are necessary. The starting points are the lens maker’s equation and the additivity rule for the inverse focal lengths of thin lens elements:

$$\frac{1}{f} = (n - 1) \cdot \left(\frac{1}{R_1} - \frac{1}{R_2} \right) \quad (27)$$

$$\frac{1}{f} = \frac{1}{f_1} + \frac{1}{f_2} \quad (28)$$

Fig. 12 (a) Primary color correction. Single lens element: Note that R_1 has a positive value (Convex to the left) whereas R_2 has a negative one (Convex to the right); (b) Achromat: Primary Axial Color Correction, Residual Secondary Axial Color; (c) Semi-Apochromat Correction.

With this, then for the blue and the red focal length of the two-lens-element system:

$$\frac{1}{f_{blue}} = \frac{1}{f_{1,blue}} + \frac{1}{f_{2,blue}} = (n_{1,blue} - 1) \cdot \left(\frac{1}{R_{1,1}} - \frac{1}{R_{1,2}} \right) + (n_{2,blue} - 1) \cdot \left(\frac{1}{R_{2,1}} - \frac{1}{R_{2,2}} \right) \quad (29)$$

$$\frac{1}{f_{red}} = \frac{1}{f_{1,red}} + \frac{1}{f_{2,red}} = (n_{1,red} - 1) \cdot \left(\frac{1}{R_{1,1}} - \frac{1}{R_{1,2}} \right) + (n_{2,red} - 1) \cdot \left(\frac{1}{R_{2,1}} - \frac{1}{R_{2,2}} \right) \quad (30)$$

If both the blue and the red focal length are to be the same, the following equation must hold:

$$0 = (n_{1,blue} - n_{1,red}) \cdot \left(\frac{1}{R_{1,1}} - \frac{1}{R_{1,2}} \right) + (n_{2,blue} - n_{2,red}) \cdot \left(\frac{1}{R_{2,1}} - \frac{1}{R_{2,2}} \right) \quad (31)$$

As both $1/R_{1,1}$ and $-1/R_{1,2}$ are positive, $(n_{1,blue} - n_{1,red})$ should be small in order not to create too high a value of the positive first term and thus make the later compensation by the negative second term less easy.

$R_{2,1}$ and $-R_{2,2}$ are both negative so that compensation of the first term is possible. At this point, it has to be decided which factor of the second term, either $(n_{2,blue} - n_{2,red})$ or $(R_{2,1} - R_{2,2})$ should bear the load of compensation. A big value of $(R_{2,1} - R_{2,2})$ means a negative lens element with small radii of curvature which causes spherical aberration and is neither easy to manufacture nor to handle. So preferably, $(n_{2,blue} - n_{2,red})$ is increased.

Thus finally it is necessary to combine, e.g., a positive lens element of N-LAK8 with a negative lens element of a glass with a small Abbe number, namely N-SF6, for primary axial color correction, see Fig. 2.

To give numbers: with N-LAK8: $n_{blue}(479.99 \text{ nm}) = 1.722974$, $n_{red}(643.84) = 1.709615$, $n_{green}(546.07 \text{ nm}) = 1.716160$ and N-SF6: $n_{blue}(479.99 \text{ nm}) = 1.829796$, $n_{red}(643.84 \text{ nm}) = 1.7974931$, $n_{green}(546.07 \text{ nm}) = 1.812659$ as well as with $R_{1,1} = -R_{1,2} = 7.5966 \text{ cm}$ and $R_{2,1} = -R_{2,2} = -18.3702 \text{ cm}$, one obtains $f = 10 \text{ cm}$ for blue and red, and $f = 9.9928 \text{ cm}$ for green.

Secondary Axial Color Correction by Selecting Glasses With Anomalous Partial Dispersion

For a two lens element system, where not only the “red focus” and the “blue focus”, but also the “green focus” are at the same point (secondary axial color correction), glasses are required with a special so-called partial dispersion. *With a grain of salt*, this quantity corresponds to the second derivative of the refractive index with respect to the wavelength – in a similar way as the Abbe number corresponds to the first derivative. Calculating the optical performance of a two lens element system with primary color correction it can be shown that this system will also display secondary color correction if both lens elements – which have different Abbe numbers – have the same relative partial dispersion, i.e., the same quotient of partial dispersion and principal dispersion, see Fig. 13(a). Note that besides the already mentioned spectral lines, the blue mercury g line (435.8 nm) is referred to here as well.

Fig. 13 (a) Significance of partial dispersion and (b) Diagram of partial dispersion for glasses. Reproduced from Schott.com, 2019. Available at: https://www.schott.com/d/advanced_optics/436c7f72-e980-44c2-b14b-0c5c952cca7f/1.8/schott-ebbe-diagramm-pgf-februar-2016-de.pdf. Downloaded 02.03.2021.

The most common definition of relative partial dispersion refers to the wavelengths is:

$$P_{g,F} = \frac{n_g - n_F}{n_F - n_C} \quad (32)$$

Combinations with the different Abbe number but the same partial dispersions are not easy to find because, in general, there is a proportionality between partial dispersion and Abbe number. There are, however, exceptions from that rule – the so-called glasses with anomalous partial dispersion – so that combinations may be found of glasses with different Abbe numbers but the same relative partial dispersion, see Fig. 13(b) (schott.com, 2019).

Two lens element systems with full primary and secondary axial color correction are called Semi-apochromatic lens, see Fig. 12(c). A suitable combination is a positive lens element of, e.g., N-SSK8 (on-line in partial dispersion map, $n_d = 50$, $P_{g,F} = 0.56$) with a negative lens element of N-KZFS11 (off-line, $n_d = 42.4$, $P_{g,F} = 0.5605$), see Fig. 2.

To give numbers: with N-SSK8: $n_{\text{blue}}(479.99 \text{ nm}) = 1.627128$, $n_{\text{red}}(643.84) = 1.614598$, $n_{\text{green}}(546.07 \text{ nm}) = 1.620676$ and N-KZFS11: $n_{\text{blue}}(479.99 \text{ nm}) = 1.649150$, $n_{\text{red}}(643.84 \text{ nm}) = 1.633952$, $n_{\text{green}}(546.07 \text{ nm}) = 1.641325$ as well as with $R_{1,1} = -R_{1,2} = 1.8389 \text{ cm}$ and $R_{2,1} = -R_{2,2} = -2.2305 \text{ cm}$, one obtains $f = 10 \text{ cm}$ for blue and red and green.

Note that the glasses selected are at completely different positions in the Abbe diagram than the above pair N-LAK8 and N-SF6.

New Materials and Technologies

Magnetorheological Finishing

For centuries, there have been only high refractive indices and splitting of refractive power among several lens elements as counter-measures against spherical aberration. This has changed with modern manufacturing technologies, e.g., magnetorheological finishing, see Fig. 14. This technology allows spherical aberration to be suppressed by giving any glass the aspherical shape required for optimal imaging (Fischer *et al.*, 2008).

Magnetorheological finishing (Schwartz, 2008) is illustrated in Fig. 15. The rotating lens touches the magnetorheological fluid, which covers a rotating wheel. In addition, the lens holder swings back and forth. This would lead to a spherical polish if the abrasive power of the fluid were constant over time. However, the viscosity of the fluid and thus the abrasive power can be adjusted by a magnetic field. By computer control of the magnetic field, aspherical polishing is achieved. Together with corresponding CNC etc., very precise aspheric lenses can be made from any glass.

Precision Molding

A low cost alternative to magnetorheological finishing is precision molding, see Fig. 16. In contrast to magnetorheological finishing, however, this technology requires special glasses (Fig. 17 (schott.com, 2019)) which can be molded at not-too-high temperatures (so-called low T_G -glasses; T_G : glass transition temperature).

Optoceramics

The development of translucent ceramics for technical applications started in the 1950s (Coble, 1959, 1961). Those high tech ceramics were made possible through the initial development of “powder metallurgy” transferred into the ceramic world (Schneider, 1991). Thus, translucent polycrystalline alumina has enabled the construction of high pressure sodium and ceramic metal halide lamps (Wei, 2007; Rea *et al.*, 2009). Through availability of starting powders with increased purity and finer particle size it was finally possible to achieve highly transparent ceramics for the use of laser oscillation in the 1990s (Ikesue *et al.*, 1995). In order to achieve this, the researchers had to decrease significantly all possible scatter sources, such as grain boundary phases, residual pores and secondary phases, which cause significant losses that prohibit laser oscillation in the translucent ceramic laser gain medium (Ikesue and Aung, 2008). Thus, using cubic materials, birefringent light scatter due to different refractive indices in the different crystal axes is avoided. The grain boundaries are engineered in such way that no light scatter occurs; and pores are reduced to the ppm level, leading to transparent ceramics with optical qualities comparable to single crystals of similar compositions (e.g., (Lu *et al.*, 2000; Lee *et al.*, 2006; Prasad *et al.*, 2007; Huhle *et al.*, 2007; Ivanov *et al.*, 2007)).

Fig. 14 Spheric and aspheric lenses.

Fig. 15 Magnetorheological finishing.

Fig. 16 Precision molding.

Within the development of imaging optics the main target is a sufficient optical quality while maintaining compact and preferably light construction of the optical system, i.e., the total number of imaging lenses must be kept as low as possible. With the current available glass melting and molding techniques, only such glass types can be produced with high quality that are located in an Abbe diagram, in which the refractive index is plotted against the Abbe number, in a certain range (**Fig. 2(a)**) (Menke, 2011). Crystalline materials and polymers show different optical positions within the Abbe diagram; thus, with transparent polycrystalline ceramics extraordinary property areas that glass currently cannot reach (Yoshida *et al.*, 2006; Kvatchadze *et al.*, 2006) are principally possible. This offers the possibility for color correction, reduced birefringence and thus smaller lenses within an optical system.

YAG ceramics are available in high optical quality both as single crystals as well as ceramic materials; however, the optical position of YAG is not unique, lying just above the magical line (**Table 2**) (Menke, 2011). They are mainly used within HID lamps.

Transparent spinel ceramics MgAl_2O_4 have been developed within different laboratories, but their optical properties are also not far from the “magical line” (**Table 2**). However, as the transmittance window for spinel ceramics ranges from ~ 150 nm to $6\text{ }\mu\text{m}$ and its mechanical properties are outstanding, they are a useful material class for application as e.g., last lens element for steppers and defense windows.

As the spinel crystal phase allows the incorporation of different ions, it is possible to tune their optical properties, especially their dispersion characteristics (**Table 2**) (Menke *et al.*, 2014), not needing to account for glass forming regions.

Transparent yttrium stabilized cubic ZrO_2 (YSZ) ceramics were first demonstrated by Tosoh Corp. (Tsukuma, 1986; Tsukuma *et al.*, 1988). Because of the presence of TiO_2 as a sintering aid, birefringence can occur in these sintered ceramics, so special post-processing procedures have to be performed, to reduce stresses (Peuchert *et al.*, 2009). The optical position of YSZ is quite unique with a high refractive index $n_d \sim 2.1\text{--}2.2$ and a $v_d \sim 30\text{--}39$ (**Table 2**), depending upon its composition (Menke *et al.*, 2009a).

Translucent and transparent perovskite ceramics of the type $(\text{Ba}\{(\text{Sn}_u\text{Zr}_{1-u})_x\text{Mg}_y\text{Ta}_z\})_v\text{O}_w$; $(\text{Ba}\{(\text{Sn}_u\text{Zr}_{1-u})_x\text{Zn}_t\text{Mg}_{1-t}\}_y\text{Nb}_z)_v\text{O}_w$ have been shown to exhibit high refractive index and Abbe number, which are useful as optical parts for optical devices, such as lenses, prisms or optical path control plates (Kintaka, 2007; Murata.com, 2021).

Another multicomponent class of cubic ceramics are those within the so-called pyrochlore structure (Menke and Peuchert, 2008; Menke and Ikese, 2009; Menke *et al.*, 2009b) showing special optical positions, especially in their dispersion (**Table 2**), and

Fig. 17 Low Tg glasses. Reproduced from Schott.com, 2019. Available at: https://www.schott.com/d/advanced_optics/316ba9d5-cd3e-46bb-937c-6bca8b06aefc/1.12/schott-abb-diagram-low-tg-jan-2018-de.pdf. Downloaded 02.03.2021.

Table 2 Optical data of different transparent ceramics

	<i>Mg-Spinel based</i>	<i>YAG based</i>	<i>Spinel Variation</i>	<i>Y₂O₃ based</i>	<i>Pyrochlore based</i>	<i>Perovskite based</i>	<i>ZrO₂ based</i>
n_d	1.72	1.83	1.85	1.91	2.04	2.05	2.16
v_d	62	52	55	36	40	30	34

useful for specialized optical applications in conjunction with PK and FK glasses; thus this is useful for application in gauss-type lens optical systems (e.g., for single-lens reflex cameras), for aberration correction.

This is a reprint of K.K. Chawla, Glass Fibers, In: Reference Module in Materials Science and Materials Engineering, Elsevier Inc., 2016, doi:10.1016/B978-0-12-803581-8.02325-0.

Fabrication

The characteristic ability of glasses to be drawn stems from their viscoelastic nature, or in other words the fact that their deformation under stress is a strong function of time and deformation rate. Glassy materials, above the glass transition temperature, T_g , show Newtonian viscosity, i.e., the stress is linearly proportional to the strain rate. This property is exploited in the drawing of glass fibers. We can write, in terms of normal stresses and strains:

$$\sigma = \eta \dot{\epsilon} \quad [1]$$

where σ is the stress, η is the viscosity, and $\dot{\epsilon}$ is the strain rate. The deformation proceeds at a constant volume, i.e., an increase in length is accompanied by a decrease in the cross-sectional area. If an incremental increase in length is dl , and the corresponding decrease in cross-section is $-dA$, then:

$$\frac{dl}{l} = d\epsilon = -\frac{dA}{A}$$

where l and A are the instantaneous values of length and cross-sectional area, respectively. We introduce the strain rate by dividing throughout by incremental time, dt . Thus:

$$\dot{\epsilon} = \frac{d\epsilon}{dt} = -\frac{dA}{A} \frac{1}{dt} = -\frac{dA}{dt} \frac{1}{A} = -\frac{\dot{A}}{A} \quad [2]$$

If F is the applied load, then from eqns [1] and [2] we can write:

$$F = \eta \dot{\epsilon} A = -\eta \dot{A} \quad [3]$$

Equation [3] states that the rate at which the fiber becomes thinner is proportional to the applied force *not the applied stress*. This means that thinner and thicker regions suffer cross-sectional reduction at an equal rate; hence, there is no tendency for preferential thinning of the drawn glass where the stress is locally raised by a local decrease in fiber cross-sectional area. Thinning of drawn viscous fibers is, thus, uniform and stable. This is different from tensile thinning of most materials, which becomes interrupted by rupture after a certain strain due to a preferential local thinning instability, known as necking.

The stability of glass fibers against localization of deformation, and hence against necking, is further reinforced by the fact that for a given load, as the viscosity increases the strain rate decreases. This has indeed very important implications in fiber drawing. In order to understand these implications we need to examine the temperature dependence of viscosity. This temperature dependence is given by:

$$\eta = A \exp(Q/RT)$$

where Q is the molar activation energy, A is a pre-exponential constant, and R is the universal gas constant. This equation indicates that the viscosity varies inversely in an exponential manner with the temperature. As thinner regions of the fiber cool more rapidly, the viscosity of such regions increases resulting in a decrease in the rate at which the thin region gets thinner. This allows the thicker regions to catch up and increases further the resistance of the drawn fiber material against necking.

Glass Fibers for Reinforcement of Polymers

A schematic representation of the conventional fabrication procedure for glass fibers is shown in Figure 1. The raw materials are heated in a hopper and the molten glass is fed into electrically heated platinum or platinum–rhodium bushings having multiple holes. Typically, each bushing contains 200 holes at its base. A constant head of molten glass is kept in the tank. The molten glass flows by gravity through these holes forming fine continuous filaments which are gathered together and passed around a fast-rotating collet, followed by drawing at a speed of 1–2 km min^{−1}. Glass flows out of a platinum bushing at a rate given by:

$$q = \frac{kh r^4}{\nu l}$$

where r is the radius, l is the length, ν is the kinematic viscosity (i.e., dynamic viscosity, η , divided by density, ρ), and h is the hydrostatic pressure generated by the head of glass in the bushing. The fibers exiting the bushing are cooled, subjected to a surface

Figure 1 Schematic of the conventional fabrication procedure for glass fibers.

treatment (using an organic size such as a starch oil), and given a stretching treatment by the take-up spool. A size, consisting of an aqueous polymer emulsion, is applied before winding on a drum.

Typically, the glass fibers have a diameter between 5 and 20 μm . The final glass fiber diameter is a function of the bushing orifice diameter, viscosity (itself a function of composition and temperature), and the head of glass in the hopper. The viscosity is generally around 100Pas for good fiberization. During the glass fiber stretching treatment by the take-up spool, the take-up speed is 50–60 ms^{-1} , which is slightly higher than the drawing speed, and thus the as-wound glass fiber suffers a stretch.

Glass filaments are easily damaged by the introduction of surface defects. The sizing treatment provides for ease of handling, protects against surface damage, and binds the filaments into a strand. In almost any fiber drawing process from a melt, the melt viscosity is by far the most important process control parameter. If a single glass filament breaks, the glass will drip across other filaments and cause a breakdown of the whole drawing process. Filament breakage can occur because of undissolved particles in the glass, abrasion, devitrification, or any instability due to changes in viscosity/winding speed (Proctor, 1971).

An important characteristic of glass fiber is its extreme flexibility, which of course stems from its fine diameter and low modulus. Textile processes of weaving, knitting, etc. can be used with fine, flexible glass fibers to produce fabrics, tapes, sleeves, and ropes. E-glass fiber has a diameter between 3 and 20 μm and is commonly used for insulation purposes as well as for reinforcement of polymers. Frequently, glass fibers are chopped to obtain short, staple fibers.

Sol–Gel Processing of Glass Fibers

The conventional processing of glass fibers, as described above, involves direct melting of raw materials, followed by drawing of the molten glass through electrically heated platinum bushings. A major problem with any direct melting process is that the temperatures involved are very high. Quite frequently, the melt viscosity at reasonable temperatures is too high to allow proper homogenization. At times the oxides show large differences in volatility and direct melting results in large losses of some of the constituents. All these problems have led to processing of ceramics and glasses via a chemical route. This allows a high degree of homogeneity on a molecular scale and consequently high-purity glasses or ceramics can be obtained. In particular, the sol–gel technique of making glass fibers has become important.

Essentially the sol–gel route for making any glass or ceramic involves the formation of the appropriate glass or ceramic structure by chemical polymerization of suitable compounds in the liquid state (sol) at low temperatures. A sol is a colloidal suspension in which the individual particles are so small that no sedimentation occurs. The particle size in a sol generally varies between 1 and 100 nm. A gel is a suspension in which the liquid medium is viscous enough to behave more or less like a solid.

The precursor material for glass fibers in the form of a gel is obtained from the sol. The unwanted residues (water, organic compounds, etc.) are removed from the gel by heating at temperatures much lower than those used in direct melting processes, and the desired glass or ceramic is obtained in an appropriate form (powder, film, fiber, etc.). As the solvent liquid is lost, the sol viscosity increases until it becomes rigid, i.e., it gels. A well-controlled rate of drying is required because of the large shrinkage that accompanies the drying process.

Fiber drawing is carried out in the course of sol-to-gel conversion. The gelled fibers are then heated to produce glass fibers. There are some very general but important points to be considered in sol and gel spinning. Spinning of dilute solutions into gels results in a minimum of polymer chain entanglement. Gelled fibers are then highly porous and elastic, and should be stretched by drawing while in a temperature gradient. This removes the solvent and decreases the porosity. The viscosity of sols and gels can also be a function of time at constant temperature; for example, when a tetraethoxysilane $[\text{Si}(\text{OC}_2\text{H}_5)_4]$ –water–hydrochloric acid–alcohol solution of appropriate composition is held at near room temperature, hydrolysis and polycondensation occur and the solution viscosity increases. Fibers can be drawn at a viscosity of about 10Pas, which occurs during the course of sol-to-gel transition. It should be pointed out that for an alkoxide solution to be spinnable (Sakka, 1982) the solution must have linear polymers and an appropriate ratio of $[\text{H}_2\text{O}]/[\text{Si}(\text{OC}_2\text{H}_5)_4]$, called the r -ratio. An r -ratio < 2 gives a spinnable solution.

Table 1 Chemical composition of some common glass fibers

Compound	E-glass	C-glass	S-glass	Cemfil
SiO ₂	55.2	65.0	65.0	71.0
Al ₂ O ₃	8.0	4.0	25.0	1.0
CaO	18.7	14.0		
MgO	4.6	3.0	10.0	
Na ₂ O	0.3	8.5	0.3	Na ₂ O + K ₂ O = 11
K ₂ O	0.2			
Li ₂ O	7.3	5.0		< 1.0

Table 2 Typical properties of some glass fibers

Glass fiber type	Density (g cm ⁻³)	Tensile strength (GPa)	Young's modulus (GPa)
E-glass	2.54	1.7–3.5	69–72
S-glass	2.48	2.0–4.5	85
C-glass	2.48	1.7–2.8	70
Cemfil	2.70		80

Chemical Composition

Silica-based glass fiber has been around for a long time. Common glass fiber is readily available commercially in a variety of different chemical compositions. Most glass fibers are silica-based ($\sim 50\text{--}60\%$ SiO₂) and contain a host of other oxides of calcium, boron, sodium, aluminum, iron, etc. They are commonly used for reinforcement of thermosetting and thermoplastic polymers. **Table 1** gives the compositions of some commonly used glass fibers in composites. The designation E stands for electrical as E-glass is a good electrical insulator besides having good strength and a reasonable Young's modulus; C stands for corrosion as C-glass has a better resistance to chemical corrosion; S stands for high silica content and S-glass is able to withstand higher temperatures than others. Most continuous glass fiber produced is of the E-glass type.

Structure

Silica-based glass is a generic term representing an interesting and versatile class of materials. Glasses of various compositions can be obtained and they show very different properties. Structurally, however, all silica-based glasses have the same basic building block: a tetrahedron made up of four oxygen ions bonded covalently to a silicon ion at the center. The composition of a single tetrahedron is thus SiO₄. Each oxygen ion is, however, shared by *two* tetrahedrons, giving the bulk composition of SiO₂. It is this basic building block that is repeated in three dimensions in silica and silica-based materials. Different repeat patterns result in different structures for the same composition. The addition of other oxides of metals such as sodium, calcium, aluminum, magnesium, etc., to silica serves to alter the network structure and the bonding, and consequently the properties, mainly a reduction in viscosity which makes for easy processing. The presence of crystalline regions is undesirable in a glass because such regions act as stress raisers. Glass fibers are quite isotropic; Young's modulus and thermal expansion coefficient are the same along the fiber axis and perpendicular to it. This, of course, is a result of the amorphous, three-dimensional network structure of glass, i. e., there is no preferential alignment of any structural units such as polymer chains along the fiber axis.

Properties

Compared with most other inorganic fibers, silica-based glasses generally have a comparatively low density. The strength can be quite high, but the elastic modulus is not very high. Thus, while the strength-to-weight ratio of glass fibers is quite attractive in comparison with other inorganic fibers, their modulus-to-weight ratio is only moderate. Typical properties of different glass fibers are summarized in **Table 2**.

Although resistance to fire and many chemicals are very attractive features of glass, moisture can decrease the strength of glass fiber. In particular, the adsorption of moisture by freshly made glass fiber results in a drastic decrease in its strength. Glass fibers are also susceptible to what is called static fatigue, i. e., they cannot withstand loads for long periods of time. This is due to the phenomenon of stress corrosion induced by the ambient moisture.

Common glass fiber such as E-glass becomes severely corroded in an alkaline atmosphere such as in cement or concrete. Some special alkali-resistant glass fibers have therefore been developed. The properties of one such fiber, called Cemfil, are given in Table 2.

Fracture

Many brittle, amorphous materials such as thermosetting polymers and silica-based inorganic glasses show some tell-tale markings on their fracture surfaces (Mecholsky *et al.*, 1977; Chandan *et al.*, 1994). Typically, the fracture surface of a glass fiber shows four distinct regions. These regions surrounding the origin point of fracture are: a smooth mirror region, a mist region of small radial ridges, a hackle region consisting of large ridges, and finally a region of extensive crack branching. It turns out that the product of strength, σ , and the square root of the distance of each of these regions from the origin of fracture is a constant. One can write:

$$\sigma R_i^{0.5} = A_i$$

where R_i are the radii of the mirror-mist, mist-hackle, or crack-branching boundaries. These radii can be related to the initial flaw depth, a , or the half-width, b , through the fracture mechanics analysis:

$$\frac{c}{R_i} = \frac{K_{Ic} Y^2}{2A_i^2}$$

where $c = (ab)^{0.5}$, Y is a geometrical constant, and K_{Ic} is the critical stress intensity factor or fracture toughness.

Applications

Glass fiber is available in a variety of shapes and forms. Some of the important ones include continuous fiber and roving, staple fiber, and chopped strand mat. Staple fibers are strands of individual filaments 200–400 mm long and are excellent for providing bulkiness for filling, filtration, etc. Chopped strand glass fibers consist of fibers chopped to various lengths, 3–50 mm, mainly for the purpose of mixing with a resin for making composites. Glass fiber MTCG-S consist of randomly dispersed chopped fibers or continuous fiber strands, held together with a resin.

Glass fibers find applications in a vast array of markets.

Automotive Market

The automobile industry is one of the largest users of glass fiber. Polymer matrix composites containing glass fibers are used to make external body panels, bumper beams, pultruded body panels and air ducts, engine components, etc. Parts made of glass-fiber-reinforced polymers are much lighter than metallic ones, making the automobile more fuel efficient.

Aerospace Market

Glass-fiber-reinforced composites are used to make aircraft parts such as wings, helicopter rotor blades, engine ducts, etc. Glass fiber has a relatively low elastic modulus. Hence, it is more common to use glass-fiber-reinforced polymer composites in the interior of an airplane rather than in primary structural parts. The radar transparency characteristic of glass has given it some key uses in the radar-evading stealth technologies.

Marine Market

Sailing boats and hulls and decks of commercial fishing boats and military mine-hunters are frequently made of glass-fiber-reinforced polymers. Glass-fiber-reinforced polyester is commonly used in making boats of all sizes.

Civil Construction

This is another large market where glass fiber is widely used. Typical applications include the use of glass fibers in polymeric resins for paneling, bathtubs and shower stalls, doors, windows, etc. Glass fibers are also used as reinforcement in a variety of household items such as paper, tapes, lampshades, etc. Some special alkali-resistant glass fibers have been developed for reinforcement of cement and concrete. Commonly, steel bars are used for such purposes. Cement, however, is very alkaline. An ordinary glass fiber such as E-glass will be severely corroded in an alkaline atmosphere, hence the need for special, alkali-resistant glass fibers (Majumdar, 1970; Hannant, 1978). The bonding between glass fiber and cement is mainly mechanical and has its origin in the shrinkage that occurs when the cement is set.

Sporting Goods

Not surprisingly, the sporting goods industry was one of the first to make use of glass-fiber-reinforced composites. Examples include bicycle frames, tennis rackets, golf-club shafts, cricket bats, skis, etc. Braided fibers in a resin matrix give high torsional stiffness to skis.

Electrical/Electronic Market

Glass fibers are used extensively in printed circuit boards, industrial circuit breakers, conduits for power cables, etc.

Biomaterial Applications

Glass fibers based on binary calcium phosphate glasses (Ahmed *et al.*, 2008) or $\text{Na}_2\text{O}-\text{CaO}-\text{MgO}-\text{Al}_2\text{O}_3-\text{B}_2\text{O}_3-\text{P}_2\text{O}_5-\text{SiO}_2$ glasses (Haaparanta *et al.*, 2015) have been used for scaffolds used in tissue engineering. The glasses enhance bone formation within highly porous scaffolds generated by randomly interwoven glass fibers.

Conclusions

Glass fibers are a very versatile class of materials. They are used extensively as a reinforcement fiber for polymeric resins such as epoxy and unsaturated polyester. The stiffness of glass fiber is lower than that of other reinforcement fibers, but it possesses the distinct advantage of combining a very high strength with low density and, most of all, a very reasonable cost. Glass fiber will continue to be used as a major reinforcement fiber well into the future. The composition, structure and property information given in this paper has been augmented by Jones and Huff (2009).

Introduction

An optical fiber is a highly flexible cylindrical structure composed of a highly transparent dielectric material designed to transport energy at wavelengths – from the visible to the infrared portion of the electromagnetic spectrum – from one end of the fiber to the other using a mechanism of total internal reflection.

When one considers that the energy of a photon in the visible/near infrared region of the electromagnetic spectrum is of the order of one electron volt and that, for elements in the lower periods of the periodic table, the energy gap between a full valence shell and an empty conduction shell is typically many electron volts, one can appreciate that valence electrons for such elements cannot be excited into the higher energy levels by the absorption of such low energy photons. As all stoichiometric compounds are filled just to the top of the valence band there is no mechanism for light to be absorbed in such compounds which consequently must be transparent. Stoichiometric materials composed of low atomic number elements are therefore the candidate materials for the fabrication of optical fibers.

Compounds such as molecular oxygen (O_2) and molecular nitrogen (N_2), silica (SiO_2), perspex (PMMA), polycarbonate, soda (Na_2O), lime (CaO), boric oxide (B_2O_3), phosphorous oxide (P_2O_5), etc., are all transparent to visible and near infrared light. The air of free-space has long been a medium for line-of-sight optical communications. Indeed all of the solid materials in the above list have been involved in the history of guided optical fiber communications when in their non-crystalline glassy form, either as individual pure substances or when mixed together in suitable combinations (Cherin, 1983). Pure silica glass, first proposed by Kao and Hockham (1966), has emerged as the main substrate material for long and short distance optical fiber communications. However polymer, sodium borosilicate, and soda lime silicate glass fibers have found minor roles in short distance fiber optics.

Light guidance in optical fibers is obtained through two mechanisms of total internal reflection (Hecht, 2005): conventional and resonant. Conventional total internal reflection occurs when light, already inside a core medium, is reflected back into the core from the interface with a surrounding less dense medium called the cladding. Sometimes the core is a uniform glass rod and the cladding is the surrounding air, as in the fibers of flexible endoscopes (Hopkins and Kapany, 1954), but more typically the core consists of the same material as the cladding but now doped with trace elements of an additional compound that slightly raises its density, and thereby its refractive index, so that the reflection can take place safely deep within the overall structure as indicated in Fig. 1.

The atomic size in the transparent medium is four orders of magnitude smaller than the wavelength of the guided light and so the transparent medium can be treated as a continuum in its interaction with this light. The “optical size” of the wave guiding core is a combination of its physical dimension and its refractive index difference with the cladding ($n_1 - n_2$), where n_1 is the refractive index of the core and n_2 is that of the cladding. This size is embodied in a parameter called the normalized frequency V , where $V = (2\pi a/\lambda) \sqrt{(n_1^2 - n_2^2)}$, where a is the core radius and λ is the wavelength. For large V -values the guiding mechanisms can be typically understood and calculated in terms of Fresnel’s laws of reflection as indicated in Fig. 1(b). However, when the V -value is small Maxwell’s equations need to be deployed for a more rigorous analysis (Gloge, 1971).

One of the earliest proposed single mode fibers was a single-material structure with an air-guiding core of pure silica suspended with minimal silica supports at the center of a hollow silica tube (Kaiser *et al.*, 1973) schematically indicated in Fig. 2(a). While unsuccessful at that time, the technological advances in the intervening years have made such air-guiding structures commercially feasible. Outwardly resembling conventional fibers, single-material micro-structured fibers consist of a cylindrical glass body with voids in the cross-section of the cladding region forming a pattern of holes running along the length of the fiber. These air-filled holes have the effect of reducing the cladding’s average refractive-index relative to that of the core so that selective doping of the core is no longer required to elevate its relative refractive index. The effective refractive index difference between the pure silica core and the holey cladding can now provide guidance by the conventional total internal reflection mechanism. These fibers are generally known as holey fibers (Monro *et al.*, 2000) schematically represented in Fig. 2(b).

In recent decades, while the basic transparent media have remained the same, a different guiding mechanism for confining the light in the core region has emerged. If, in a holey fiber, the pattern of holes is arranged in a regular spatial pattern of constant pitch, Λ , and where the pitch is not much different from the wavelength of the propagating light, then a resonant reflectivity can be achieved. Just as atoms in a crystal structure reflect X-rays of a wavelength similar to the atomic spacing, corresponding to the Bragg condition, so can optical fibers with a regular spatial pattern of features incorporated into its cross-section reflect light back into a core region that itself corresponds to a “defect” in the regular pattern. The core region can be either void or solid so either air-guidance or glass-guidance can be achieved in such fibers. Fibers with this second guiding mechanism are referred to as photonic band-gap fibers or photonic crystal fibers (Birks *et al.*, 1997) and are schematically represented in Fig. 2(c).

In all optical fibers, the transparency is due to the electronic band-gap, and the guidance is due either to the conventional refractive index difference or to a photonic band-gap.

Silica Fibers

A concentration of 1 mol% of germania (GeO_2) raises the refractive index of silica by approximately 0.1% (Mitschke, 2016). The standard telecommunications fiber typically has a germania-doped silica core surrounded by a lower index cladding of pure silica, each with a circular cross-section. The cladding diameter for this standard fiber is 125 μm . This is the basic structure that will form the backbone of this review. Fibers made from other materials and made for other purposes will be mentioned as required. Optical fibers can be conveniently divided into two subclasses called single-mode (with comparatively small cores) and multi-mode (with comparatively large cores). The demarcation between the two depends on the “optical size” of the core relative to the operating wavelength. As mentioned above the core’s “optical size” is a function of the core’s diameter, the refractive index difference between the core and the cladding, and also takes account of the spatial distribution or ‘profile’ of that refractive index.

Single-mode fibers have core diameters of between 4 and 10 μm with values of relative refractive index difference Δ of about 0.1%, while multimode fibers have core diameters of between 50 and 100 μm with Δ values of about 1%. Within the core, the refractive index distribution can be uniform (step-index), or it can be gradual (graded-index), as indicated in Fig. 3. Indeed, for reasons that will become clear, in standard optical telecommunications jargon the “step index” is synonymous with the single-mode fiber, and the “graded index” is synonymous with the multi-mode fiber. The cladding index is typically uniform, in each case however for wave-guidance, it is necessary that the core index be greater than the cladding index for at least some region of its cross-section. For the majority of applications, most of the light energy propagates in the core and only a small fraction of it travels in the cladding. Any outer protective jacket is optically isolated from the core, so we can usually ignore its effects in theoretical calculations in which an unbounded cladding is assumed. For the purposes of this review the properties of the protective jacket will not be considered in any great detail.

Fig. 3 Refractive index profile of standard telecommunications fibers. (a) Step-index (Single-mode), (b) Graded-index (Multi-mode).

Light Propagation

Optical fibers are typically weakly-guiding (Gloge, 1971); this term takes for granted that the refractive index difference between the core and the cladding is less than 1%. The circular step index core is canonical and calculations on it can be expressed in analytic form. The circular step index single-mode fiber is particularly tractable and, indeed, single mode cores with other refractive index profiles can fortuitously be expressed in an “equivalent-step” form (Millar, 1981).

Geometrical optics can give a reasonable insight into how light is guided in these weakly guiding fibers. With reference to Fig. 4, the critical angle, θ_c , for rays of light in the core region of refractive index n_1 incident on the boundary of the lower index cladding n_2 , above which light is totally internally reflected back into the core is given by $\sin \theta_c = n_2/n_1$. Since n_1 and n_2 are nearly equal, θ_c must be very close to 90° . Remembering that the angle of incidence is measured with respect to the normal to the boundary, this means that only those rays of light that are almost parallel to the boundary are totally internally reflected.

A mode can loosely be identified with the family of rays all propagating at the same angle. The number of modes that can propagate in the step-index fiber is related to the optical size of the core or its V-value, as mentioned above. Only one mode propagates on the step-index fiber for V-values of less than 2.405; this is the fundamental mode and it propagates at all frequencies (Snyder and Love, 1981). The fundamental mode has the shape of a Gaussian or Normal distribution, with the maximum in the center of the core and the evanescent tails of the distribution extending into the cladding. Single-mode fibers are those designed to propagate only the fundamental mode and are usually designed to operate as close to the V-value of 2.405 as possible where the fraction of modal power propagating in the core is about 80% with the remaining 20% propagating in the cladding. At smaller V-values the modal shape is more spread out and the mode is less tightly confined to the core.

The exact radial distribution of the electric field of each mode is found from the solutions of Maxwell’s equations. For the circular step-index fiber the modal field solutions are oscillatory in the core and are given by the Bessel functions, while the evanescent cladding fields are given by the modified Bessel functions. The modal eigenvalues, or propagation constants, are obtained by numerically matching the fields and their derivative at the core/cladding boundary. Unlike the fundamental mode, each other mode has a cut-off frequency below which it is no longer guided, so the number 2.405 is actually the cut-off V-value of the second mode. As the frequency increases above the cut-off point of a mode, that mode becomes more tightly confined into the core and therefore is more strongly guided (Snyder and Love, 1981).

Multimode fibers typically have V-values above 50 and can have over one thousand modes propagating and so modal analysis can prove very cumbersome. However since their ‘optical size’ is large, it is found that the simpler geometrical, or ray optics, as described above, are appropriate.

Transmission Bandwidth

The bandwidth of a fiber is determined by the combined influence of its structural parameters, its materials properties, and on the chromatic and intermodal dispersion of the propagating signal.

Multimode Fibers: The bandwidth of multimode fibers is basically determined by the intermodal dispersion as the different group velocities of the different modes causes the temporal spreading of an input pulse of light as it propagates along the fiber. It thereby limits the rate at which sharp input pulses can be injected into the fiber and be successfully detected as separate pulses at the output end. However the effective optical path of each mode can be made the same by suitably grading the refractive index of the core so that the maximum index lies along the fiber axis and the index falls to zero at the core/cladding boundary. In such a case the low order modes – with their angles almost parallel to the axis – travel the shortest paths but in the dense medium, while modes at higher angles to the axis travel longer paths but now in a less dense medium. The group velocities of the different modes can thereby be equalized. The optimum refractive index profile is found to be close to the parabolic shape, as in Fig. 3(b), although the slightest distortion of the profile can radically degrade the performance (Cherin, 1983). Multimode fibers have still some relevance in short-haul applications but have been superseded in long-haul networks by single mode fibers.

Fig. 4 Geometrical optics description of total internal reflection.

Single Mode Fibers: Chromatic dispersion is the dominant bandwidth limiting effect on single mode fibers and is caused by propagation-delay differences among different spectral components of the signal; it includes material dispersion and waveguide dispersion (Marcuse, 1979) which is associated with the guidance effects of the fiber structure. Material dispersion arises because the refractive index of the material is different for different wavelengths, and waveguide dispersion arises because modal confinement also varies with wavelength. Profile dispersion arises because the core materials and cladding material may have different variations with wavelength, but this additional dispersion tends to be small compared with the other two dispersion effects (Gambling *et al.*, 1979).

Fortunately, dispersion from different effects can compensate each other in their overall contribution to chromatic dispersion in single-mode fibers. By balancing the (negative) material dispersion against the (positive) waveguide dispersion, it is possible to locate a wavelength for which there is zero chromatic dispersion in these fibers. Thus, while in bulk germania-doped silica for which the material dispersion is zero near the wavelength of 1300 nm (Payne and Gambling, 1975), by a suitable choice of core diameter and relative refractive index difference, the wavelength of minimum chromatic dispersion can be positioned in the 1500–1600 nm region where the transmission loss is lowest. Fibers that achieve this effect are referred to as dispersion-shifted fibers and can have a sophisticated double cladding structure, so-called doubly-clad or W-fibers (Monerie, 1982), as indicated in Fig. 5(a). The more sophisticated core/cladding structures of multiply-clad fibers (Cohen *et al.*, 1979), see Fig. 5(b), can achieve almost perfect cancellation of material dispersion by the waveguide dispersion over an extended spectral range and are referred to as dispersion-flattened fibers (Okamoto *et al.*, 1979).

Strictly the fundamental mode of a perfectly circular fiber is a superposition of the two identical mode shapes corresponding to two orthogonal polarizations each propagating with the same propagation constant which can generally be treated as one entity. However birefringence effects, arising when each polarization of the fundamental mode has a different propagation constant, due to core-ellipticity or strain-induced anisotropy, may limit the bandwidth at wavelengths where the more dominant chromatic dispersion is a minimum. Such restrictions on bandwidth in single-mode fibers can be removed if only one of the polarization states of the fundamental mode is allowed to propagate. Truly single-mode propagation may be achieved in high-birefringent fibers of which there are three main types: the elliptical core (Shibata *et al.*, 1983), the bow-tie (Birch *et al.*, 1982), and the PANDA (Sasaki *et al.*, 1986) fibers, illustrated schematically in Fig. 6(a), (b), and (c), respectively. However such fibers have not found widespread use in optical communications networks.

Micro-structured fibers: While it is not anticipated that micro-structured fibers will replace conventional fibers in long-haul applications they do display interesting dispersion behavior. Holey fibers with a large effective refractive index difference (i.e. with a large holey area) can have its waveguide dispersion dominate the material dispersion and so shift the zero dispersion wavelength to wavelengths shorter than 1300 nm, which is impossible in conventional germania doped silica fibers (Monro *et al.*, 2000).

Another recent innovation has been the multi-core fibers which have already been demonstrated with up to 31 single-mode cores assembled, in much the same manner as the above micro-structured fibers, in a cladding with the conventional diameter of 125 μm . These fibers are proposed as a new space division multiplex (SDM) technology for next generation communications (Hayashi and Nakanishi, 2018).

Loss and Gain Mechanisms in Optical Fibers

Transmission loss is one of the most important properties of an optical fiber as it determines, to a large extent, the separation between the repeaters required to regenerate the transmitted signals in long-haul links. In a repeater the optical signal is converted into an electronic form in which it can be conveniently amplified and then reconverted back into an optical signal to continue its journey. These opto-electronic repeaters are expensive so the cost of any system is significantly affected by fiber losses which determine the number of such repeaters required in an optical communications link.

The different loss mechanisms are due to material effects such as absorption and scattering, and bending effects due to jacketing and installation. However, the expensive opto-electronic conversion stage can be eliminated from optical communications links by inserting an optical fiber amplifier into the link in which the signal remains in its optical form throughout. Light amplification can be achieved in the standard germania-doped silica core by exploiting its slight inherent non-linearity through stimulated

Fig. 6 Polarization-maintaining fibers. (a) Elliptical core, (b) Bow-tie, (c) Panda.

Raman scattering (Stolen *et al.*, 1984). Alternatively by doping the core region with an element from one of the higher periods of the periodic table, typically one of the rare-earth elements, for which the energy gap between the valence and conduction levels is of the order of one electron volt, thereby matching the energy of the propagating photons, it is possible to achieve light amplification or gain of the transmitted signal by stimulated emission of radiation in a single pass through this special fiber (Koester and Snitzer, 1964).

Materials effects

Absorption: There are two main resonance absorptions (i.e., regions of anomalous dispersion) in silica that bound the region-of-transparency relevant to optical communications; one is related to the electronic transition between the valence band and the conduction band, and the other is due to molecular vibrations in the tetragonal structure of SiO_4 units in the silica glass network. The electronic transition occurs in the UV region with a tail that extends into the visible. The bonds in the tetrahedral building blocks are characterized by various types of vibrational modes whose resonance wavelengths and their harmonics are distributed throughout the IR region. At the wavelengths of interest in optical communications the absorption losses due to the electronic transition are negligible in the range from 1300 nm to 1600 nm whereas the absorption due to the molecular vibration prohibits transmission in silica beyond wavelengths of about 1675 nm. The global loss minimum in silica is about 0.2 dBkm^{-1} which occurs at 1550 nm (Miya *et al.*, 1979).

There can be additional absorption losses from impurities such as Si-OH species (with peaks at 950, 1250 and 1390 nm) and transition metal ions. All of these additional losses have virtually been eliminated from the modern manufacture processes of silica optical fibers. However their traces remain in the terminology; wavelengths less than 950 nm are referred to as the first-window, wavelengths less than 1390 nm are the second-window, and wavelengths centered on 1550 nm are the third-window. The complete region of transparency of silica is now available for optical communications. The range of wavelengths from 1260 to 1360 nm is now referred to as the O-band (O for original), the range from 1360 to 1460 nm is the E-band (E for extended), the 1460–1530 nm range is the S-band (S for short wavelength), the range from 1530 to 1565 nm is the C-band (C for conventional) and is also referred to as the Er-window, the range from 1565 to 1625 nm is the L-band (L for long wavelength), and finally the range from 1625 to 1675 nm is the U-band (U for ultra-long wavelength). There is no letter designating the earliest wavelengths centered at 870 nm where the losses are too great for modern optical communications.

Scattering: In addition to the inherent absorption loss due to the two resonances that frame the relevant region-of-transparency in silica, there is the loss due to Rayleigh scattering (Stacey, 1956). Rayleigh scattering in amorphous glass arises from the inherent random nature of the thermodynamic fluctuations in its density or refractive-index and it cannot be eliminated. Rayleigh scattering loss scales with the negative fourth power of the wavelength (λ^{-4}), so it becomes rapidly smaller for longer wavelengths. Routine measured losses in mass-produced silica fibers range from about 1.0 dBkm^{-1} at the 1000 nm wavelength to about 0.2 dBkm^{-1} at the 1550 nm wavelength.

Proposals to use heavier molecules than silica such as the fluorides (France *et al.*, 1987) and the chalcogenides (Sanghera and Aggarwal, 1997) in order to shift the infrared tail to longer wavelengths and thereby exploit the ultra-low Rayleigh scattering in this region have not succeeded in displacing silica as the material of choice for fiber optics. The mechanical properties of fibers made from these materials cannot seem to compete with those of silica either.

Bending losses

Micro bend effects result from the statistical micro-deviations of the fiber from a straight line which arise in manufacturing processes such as coating and cabling. Microbends of the order of 100 nm to 1 μ m tend to be significant contributors to loss (Gardner, 1975).

Macro bends, with the bend radii of the order of centimeters, are due to unavoidable bends in the installed cables. One can loosely understand the loss effect in ray-optics terms. On entering the bent section of the fiber the angle of incidence of the ray at the core/cladding boundary on the outer side of the bend reduces, and if the new angle of incidence is less than the critical angle then the ray is refracted into the cladding and power is lost, or leaked, from the guided mode.

Amplifier fibers

Raman fiber amplifiers (RFAs) exploit stimulated Raman scattering due to the slight non-linearity of the standard transmission fiber, or alternatively requires a short length of highly non-linear fiber to serve as the amplifier.

Rare-earth doped optical fiber amplifiers rely on stimulated emission provided by the downward electron transitions in the rare-earth ions doping the core and sometimes the regions of the cladding adjacent to the core. The ions are excited, or pumped, with a lower wavelength (higher frequency hence higher energy) source than the signal wavelength. Of all the possible rare-earth elements, only erbium (Er^{3+}) operates at suitable telecommunications wavelengths when silica is its host glass (Mears *et al.*, 1987). Erbium doped fiber amplifiers (EDFAs) offer a broad transition at the wavelength of 1550 nm which fortuitously corresponds to the wavelength of least transmission loss (C-band) on silica fibers.

Fiber Fabrication

In this section the material requirements and fabrication techniques leading to the production of low-loss and high-bandwidth optical fibers are described.

The material systems must be capable of providing a core with a slightly higher refractive-index than that of the cladding in a stable insensitive structure that is capable of being drawn into a fiber. The core and cladding materials must therefore have similar viscosities and coefficients of thermal expansion. The material must be low-loss in the regions of the wavelength spectrum where semiconductor diodes are available. To obtain high transmission bandwidth, the refractive-index distribution in the core must be capable of being profiled. These material requirements limit the field of candidate materials to glasses and plastics. In turn, many plastics are excluded from consideration because the presence of hydrogen in their structures give rise to very high losses and their molecular size leads to very high scattering losses. For this reason emphasis is mainly confined to inorganic glasses.

Modern optical communications had its inception with the research paper from the Standard Telecommunications Laboratories (UK) (Kao and Hockham, 1966) which argued that the strong optical attenuation in glass was not an intrinsic property of the glass but was due to impurities in its chemical composition. It further suggested that silica was the most suitable candidate glass for optical fiber as its region-of-transparency matched the wavelength available from the recently invented semiconductor laser diode. Indeed it had been the demonstration of the ruby laser (Maiman, 1960) providing a coherent optical carrier wave that had prompted the investigation of the possibility of high bandwidth optical communications in the first place. Optical wavelengths had the promise of orders-of-magnitude more information bandwidth than the micro-wave radiation then being concurrently developed for satellite communications during the space-race.

Concentrating here on the high-silica fibers, emphasis will be placed on the two-step process of first producing the high purity preform and then drawing the preform into a fiber. The preform is a large scale rod of glass containing the core and cladding materials incorporated during a deposition process to obtain the required spatial distribution of dopant material for the required fiber refractive index profile. The rod could be up to 1 m long with a diameter of between 10 to 50 mm. The step of scaling down the preform to yield the fiber is referred to as fiber drawing. In this step the rod is softened by heating and then stretched out by pulling in a fiber-drawing machine. Both steps will now be described in more detail.

Preform Fabrication

There are several alternative ways of making the preform that are proprietary to different manufacturers and that all rely on vapor phase processes. These techniques use pure silica as a substrate material and then add trace amounts of dopant to it in order to change its refractive index and allow a waveguide to be formed. In a typical vapor phase reaction, high purity chloride precursors such as SiCl_4 , GeCl_4 , POCl_3 , BCl_3 , purified by distillation, undergo a high-temperature oxidation process or hydrolysis to form oxides of silicon and the dopant elements. For oxidation the completed chemical reactions are as follows (Partus and Saifi, 1980):

Gaseous chlorine evaporates, and solid silicon dioxide condenses as an amorphous substance on cool surfaces and can form the fused silica glass at suitable temperatures. Dopant materials such as GeO_2 and P_2O_5 raise the refractive index of silica, whereas B_2O_3 reduces it.

The different preform fabrication techniques are classified as to whether the glass material deposition is an inside or outside process. For the outside process, the glass material is deposited directly onto a target surface called a bait rod, while in the inside process glass deposition occurs on the inside of a fused silica tube.

Outside vapor deposition (OVD) or the soot process was developed by Corning Glass Works (Keck and Schultz, 1973). Glass is deposited in thin layers on the outside of a massive cylindrical bait rod of aluminum oxide. The precursor chemicals are fed into a burner flame so that sub-microscopic glass particles are generated and condense on the surface of the bait rod. Meanwhile the bait rod is rotated and translated so that a uniform layer is formed. The cycle is repeated so that many such layers are deposited and during the deposition the concentrations of dopant for each layer are adjusted so that the resultant structure already contains the dopant profile as required for the desired refractive index profile of the finished fiber. Each deposited layer is porous (soot) so the assembly is then heated to allow evaporation of the trapped gasses including any humidity that may have entered from the hydrocarbon flame. Further heating sinters the glass layer so that porosity is removed. Once the glass is compact, the bait rod can be extracted and the preform tube collapsed into a solid rod.

Developed at Bell Laboratories, the most common inside process is modified chemical vapor deposition (MCVD) (MacChesney *et al.*, 1974). As in the OVD case, the idea is to form glassy layers of differently doped silica on the inside surface of a silica tube which will later become the outer part of the cladding. Gaseous vapors of the precursor chemicals are passed through the bore of the tube along and around which a burner is passed. In the heated zone porous glass is thereby deposited in thin layers onto the inner surface of the tube. Here no residual gas or water vapor can be trapped because the precursor chemicals do not come into contact with the flame. The porous glass is then sintered and the hollow tube is collapsed into a solid rod. In this case the starting tube needs to be of very high purity and uniformity. There can be burn-off of dopants from the innermost layer during the collapse phase leading to a dip in the profile of the eventual refractive index. Fortunately such a dip has very little effect on the shape of the propagating mode (Hussey and Pask, 1982).

Plasma chemical vapor deposition (PCVD) developed by the Phillips Research Laboratories (Geittner *et al.*, 1976) is a variant of MCVD where the gas burner is replaced with a microwave generator which generates a plasma inside the tube. The plasma is constant enough that rotation of the tube is not required and sintering is not required as the layers of glass are deposited free of pores. Very precise control of the refractive index profile is achievable with this process in which it is not uncommon to deposit 2000 layers. The central dip in the refractive index also occurs here during the final collapse stage.

Vapor phase axial deposition (VAD) was developed in Japan (Sudo *et al.*, 1978) and is quite different from the ones described earlier in that the glass is deposited at the end of a seed rod and the structure is allowed to grow by extending the length of the rod. The cross-sectional refractive index profile is obtained through an elaborate geometry of burner flames and positions of nozzles that bring in the precursor chemicals. Constant turning provides the required rotational symmetry. The deposition is initially porous so the soot is sintered by pulling the entire rod through a suitably heated zone and yields the preform that requires no further collapse.

Preforms for the microstructured fibers can start with a solid rod into which holes may be drilled to achieve the desired cross-sectional pattern. More commonly the preform is assembled by stacking a number of same-material glass tubes together to form a bundle. One can replace individual tubes with solid rods or with tubes of thicker walls to achieve the desired cross-sectional pattern. The central tube can either be replaced with a rod or left void if solid-core guidance or air-guidance, respectively, is desired. The stack is then fused together and may in turn be inserted into a solid thick-walled tube, again of the same material, before being drawn into the eventual fiber. Recently the technology of 3D printing has been applied to the production of microstructured preforms and has the feature that the individual holes produced need not necessarily be circular (Chu *et al.*, 2019). The opportunities that such flexibility provides have yet to be explored.

Each of the above processes yields a preform which is a short fat scaled-up model of the desired fiber cross-section. A 1 m long preform of 25 mm diameter will yield 40 km of standard 125 μm diameter fiber.

Fiber Drawing

The drawing process must yield a fiber whose diameter is precisely controlled. In addition the fiber's strength must be preserved by applying a protective coating which shields the newly drawn fiber from mechanical abrasion and adverse atmospheric effects; it also helps minimize micro bending loss. A drive mechanism feeds the preform into a heated region where it necks down to form a fiber which is pulled from the hot-zone in which the preform is brought to its working temperature, defined as corresponding to a viscosity of approximately 10^4 poise, which is in the range of 1700°C to 2000°C for silica. The important requirement that the constituent glasses in the fiber cross-section have similar viscosities and thermal expansion coefficients is automatically satisfied in weakly guiding fibers and in single-material fibers. The diameter of the fiber is measured at a point shortly after it is formed and this measured value is fed into an elaborate closed loop control system. Within the controller the measured fiber diameter is compared with a desired value thereby generating a signal to adjust the drawing speed such that the fiber diameter reaches the desired value. Modern production processes are capable of producing 125 μm diameter fibers to within an accuracy of 0.1 μm . After the diameter is measured the protective coating is applied to the fiber by way of an extruder. The protective coating may

consist of two layers: an inner soft and pliable layer, and an outer hard layer resistant to abrasion. Epoxides and polyimides or acrylates and silicones are used. The coating material is then cured and the fiber may be subject to further mechanical testing before it reaches the drawing mechanism where it is wound onto a spool.

Introduction

The physical and chemical properties of conventional glasses have been analyzed for a long time and their applications are well known (Scholze, 1991; Zarzycki, 1991). Glasses are generally used in the field of optical materials and containers but also as fibers for reinforcement and some peculiar applications such as nuclear wastes storage. Usual glasses (window glass and other silicates) are generally done by a multiple steps process including, the melting of the different oxides at a high temperature followed by an refining and finally quenching. The last step causes the freezing of the amorphous structure of the melt. It is followed by an annealing treatment which relaxes the thermal strain. In the last decades a new kind of glasses has been extensively studied in literature. These amorphous materials are no more prepared using the classical melting and refining processes but by the sol-gel method.

In the early 1980s (Gottardi, 1982) it was demonstrated that the 'sol-gel process' could be a way to synthesize materials as different as ceramics, glasses or composites. Since then, three books (Klein, 1988; Brinker and Scherer, 1990; Sakka, 2005) have shown the possibilities of these techniques to allow the synthesis of materials in the form of bulk products, films, or fibers. The sol-gel synthesis was reported as early as the nineteenth century by Ebelmen (1845), who reported the formation, by slow hydrolysis of silicic esters, of a transparent solid which showed no evidence of crystallization. In the 1930s sol-gel dip coating was mentioned for the first time in the patent literature (Geffecken and Berger, 1939). Perhaps the reason for so few investigations in the past into the use of sol-gel methods in glass technology is that traditional ideas about glass formation have always involved high temperature. As already mentioned, the classical procedure for making glasses includes a step at elevated temperature which ensures that the raw materials have reacted and dissolved and the liquid structure is then preserved by super cooling of the melt. In the sol-gel route this high temperature step is eliminated, the homogenization is achieved in the solution at room temperature and cross-linking and preservation of the liquid structure is accomplished by the gelling step. Further heat treatments only serve to remove organic species, hydroxyls and porosity.

What is the sol-gel process and why is it so attractive for materials scientists? A precise definition of the sol-gel route is difficult because it corresponds to a variety of techniques and processes in which one of the steps uses material in the form of a gel. Thus, instead of giving a definition, it is more relevant for what follows to understand what is meant by a gel. A gel will be defined as a 'two-phase medium composed of a solid and a fluid, obtained by an isotropic and progressive aggregation from a solution.' Obviously, this definition is restrictive but it has the advantage of describing exactly the kind of material of interest in this chapter. The sol-gel process has several flexibilities and unique features that are of significant importance in preparing ultrapure homogeneous glasses:

- The high purity of the starting compounds can be preserved during the process. The use of synthetic organometallic chemical compounds guarantees high purity. Because of the expected high purity of gel derived glasses, an obvious interest of the sol-gel route is the possibility of producing optical glass components (mirrors, lenses or preforms for optical fibers).
- For multicomponent systems, rapid homogenization of the different chemical species can be achieved at a molecular level by chemical reactions in the low-viscosity starting solution.
- In the case of compositions leading to glass, the gel is amorphous and can be transformed into a glass over a low-temperature range, without melting or refining. The sintering treatment is carried out at temperatures one-third to one-half lower than those required for melting of the glass-forming components, practically in the vicinity of the glass transition temperature. This lower processing temperature reduces the risks of contamination and losses of volatile components (e.g., B_2O_3 , P_2O_5).
- The morphology of the product, film, fiber or bulk material, can be controlled by the adjustment of the viscosity at room temperature. The use of liquids allows the ready fabrication of thin films and fibers.

The purpose of this chapter is to explain through an example (the conversion of an aerogel into a glass) the different steps of the synthesis and transformation of gels as precursors for glass preparation. A great many technical and commercial products contain the glass-former silica. For this reason we will describe the preparation of a silica glass, the preparation of other glasses follows similar lines. In the last part of this paper we will give an example of the synthesis of porous glasses for the confinement of nuclear wastes.

Principle of the Sol-Gel Glass Route

The challenge of the sol-gel glass process is to obtain a solid material that is dense, inorganic, and amorphous from a room-temperature liquid (not a melt) which is generally a homogeneous mixture of organic compounds. Several transformations of the liquid compounds are necessary, as shown schematically below:

Solution

Gelation

- Destabilisation of a colloidal sol
- Hydrolysis and polycondensation $\text{Si}(\text{OR})_4$

↓

Wet Gel

Drying

- Classical drying (xerogel)
- Supercritical drying (aerogel)

↓

Dry gel

Densification

- Hot pressing
- Sintering

↓

Glass

The first step is the formation of a gel from the solution. There are two classical ways of obtaining silica-based gels: the destabilization of silica sols or the hydrolysis and polycondensation reactions of an organometallic compound of silicon (Section 3). Both methods lead to non-crystalline materials containing substantial amounts of water and organic species which can be eliminated by suitable drying treatments. The drying process can be carried out at ambient temperature but during this drying stage considerable shrinkage occurs converting the wet and soft gel into a dried and harder porous solid (xerogel). The drying procedure is crucial and must be performed extremely slowly because it induces capillary phenomena which can destroy the gel network and lead to the breaking up of the solid network.

To avoid these problems supercritical drying is required, as described in Section 4. After supercritical drying, the gel (which is called an aerogel) is a solid material, amorphous, but extremely porous (80–99% porosity) (Aegerter, 2011). The last step of the transformation is a densification heat treatment necessary to convert the dried gels into solid glasses devoid of porosity (sintering) (Section 5). Gels which are originally non-crystalline may crystallize during the heat treatment. The successful formation of a glass is the result of a competition between phenomena which lead to densification and those which promote crystallization (Section 6). In Section 7, we propose the use of these porous materials as host matrices for the synthesis of multi-phase materials (doped glass, glass-ceramics, composites, etc.).

Gel Synthesis

There are two methods for the preparation of gels which can be used for making glasses. The first one is the destabilization of a colloidal sol (Iler, 1979). This method is based on the preparation of stable sols in a liquid medium using non-crystalline particles of colloidal sizes. The destabilization occurs by a modification of the pH or an increase of temperature which favors the collision between colloidal particles. The second method involves the hydrolysis and polycondensation reactions of an organometallic compound $\text{Si}(\text{OR})_4$ which is dissolved in alcohol in the presence of a limited amount of water ions (Brinker and Scherer, 1990). This method is more suited for obtaining a pure glass, owing to the higher purity of the organometallic compounds compared to colloidal sols which contains traces of alkali.

The hydrolysis reaction replaces the alkoxide groups OR with hydroxyl groups OH:

By condensation reactions, two silanol groups give rise to siloxane bonds Si–O–Si:

In reality, the reactions are simultaneous and incomplete. A part of the organic groups are still present after gelation and the polycondensation leads to the reticulation of chains containing unreacted silanol groups. Finally, the chemical composition of the gel is not SiO_2 but $\text{SiO}_x(\text{OR})_y(\text{OH})_z$. In a certain sense the OR groups play the role of non-bridging oxygen in alkali-containing glasses. Therefore, such organic components can also be characterized as network modifiers. The most common alkoxides used in the literature are tetraethoxysilane, $\text{Si}(\text{OC}_2\text{H}_5)_4$, and tetramethoxysilane, $\text{Si}(\text{OCH}_3)_4$.

In the case of multicomponent glasses, we can replace the silicon atom by other network formers known in glass science. The net reaction is customary represented by

where M is a network-forming cation (M=B, P, Ti, Al, Zr). Some glass components (elements of groups 1 and 2) do not form suitable alkoxides. Water-soluble salts such as acetates and nitrates can be used for these constituents (James, 1988; Brinker and Scherer, 1990; Sakka, 2005).

Drying Process

After gelation, the gel is a two-phase medium containing the solid network and the liquid (alcohol–water). During classical drying (evaporation of the liquid) capillary forces collapse the skeletal gel structure, giving rise to a hard glassy product (xerogel) with a significant shrinkage. Moreover, drying induces the formation of cracks and the breaking up of the material. Various alternatives to slow drying are methods involving a favorable compromise between the capillary forces and the mechanical resistance of the gel network: strengthening the gel by reinforcement, reducing the surface tension, enlarging the pores, etc. (Toki, 1988; Brinker and Scherer, 1990).

However the most efficient method is the supercritical drying. The goal of supercritical drying (SCD) is to eliminate these capillary forces which occur when the vapor/liquid surface is in contact with the solid part of the gel. The magnitude of these stresses is dependent on the interfacial energy γ of the liquid. It is possible to suppress γ if the pressure and the temperature pass over the critical point of the liquid. In this pressure and temperature domain, gas and liquid are no longer distinguishable and the γ value becomes zero. According to the temperature and pressure required, the experiments are performed in an autoclave. Supercritical fluid drying was initially developed by Kistler (1932). For the material obtained, he proposed the term ‘aerogel’ to indicate that air now replaces the liquid previously filling the fine texture of the solid network. After supercritical drying, the silica gel is a dry material, very porous (80–99%), and brittle compared to silica glass. The mechanical strength and elastic moduli are a factor of 10^3 – 10^4 (depending on the porosity) lower than those of silica glass (Woignier *et al.*, 2011a). IR and Raman spectroscopies show that the dried gels contain hydroxyls and organic species either as adsorbed or structural groups. The scattering techniques: Small Angle Neutron or X-rays Scattering (SANS, SANS), gives information on the structure and degree of compaction in the clusters forming the gel network. The aerogel network can be described as an assembly of clusters (~ 50 nm). The clusters can be fractal (fractal dimension $D_f \sim 2$), built by the aggregation of small particles (~ 1 – 2 nm) (Marlière *et al.*, 2001). The porosity is totally open and covers the range of meso- and macroporosity (Anes *et al.*, 2014; Reichenauer *et al.*, 2001).

Although the gel network is rather different from that of silica glass, Raman, IR, and NMR spectroscopies, which characterize the molecular structure, reveal vibrational bands and peaks identical to those observed in vitreous silica. The next step in the process converts this porous and somewhat organic material to dense silica avoiding crystallization.

Aerogel–Glass Transformation

As previously mentioned, gels are made of amorphous silica, like in glass, but the main differences are the huge porosity and the high content of hydroxyl and organic groups of the gels. Thermal treatments should eliminate the undesirable chemical species and the pores. Thermograms obtained by differential thermal analysis (DTA), thermogravimetry and dilatometry show three temperature ranges related to aerogel evolution. The DTA endothermic bands within the range 25–200 °C are attributed to vaporization of water and alcohol. Exotherms in the temperature range 250–500 °C are attributed to the oxidation of the organic species. Dilatometric data show that the conversion to dense glass by sintering begins in the temperature range (500–1000 °C) and the densification increases rapidly around 1000 °C (Woignier *et al.*, 2000), a temperature much lower than the melting temperature of silica quartz (1610 °C).

IR spectroscopy is a useful tool to follow the structural and chemical changes during the gel to-glass conversion. The transmission spectrum at room temperature exhibits several absorption peaks related to adsorbed water, silanol and organic groups. The evolution of the spectra can be directly related to the thermal analysis; the peaks attributed to molecular water and to organics can be removed at relatively low temperature. After heat treatment at 1100 °C, the spectrum is identical to that of a conventional silica glass with a high OH content (~ 5000 ppm). The modification of the mechanical properties is not related to the temperature range but rather to the densification state. At low temperature, before the sintering temperature range, the mechanical properties are not strongly affected by the heat treatment. However, the elastic Young's modulus and the mechanical strength increase by a factor of 10^3 – 10^4 with densification and become identical to those of silica glass.

In the same way, when densification proceeds, SANS data reveal the structure evolution of the gels (Woignier *et al.*, 1999). The cluster size decreases, the particles grow and D_f tends toward a value of 3. These transformations indicate a rearrangement of the clusters toward a higher degree of compaction. The sintering proceeds by a viscous flow mechanism (Scherer, 1977).

Characterization of Gel-Sintered Glass and Comparison with Conventional Glass

The gel-sintered glass obtained after a controlled heat treatment above 1000 °C is dense, transparent, and exhibits physical properties identical to those of melt-quenched silica. Transmission measurements in the UV and IR spectral ranges indicate the absence of transition metal impurities and confirm the good optical quality of the gel-sintered glass. The most important difference

is the high OH content which can promote foaming and crystallization at temperatures higher than 1200 °C. If necessary, a dehydration heat treatment (halogenation) can be used in order to eliminate completely the OH content (Phalippou *et al.*, 1984).

It has been supposed in the literature that glasses produced from gels can differ from conventionally melt-quenched glasses. Previous work (Konijnendijk *et al.*, 1973; Mukherjee, 1988) on the preparation of alkali borosilicate glasses by the melting of gel (not sintering) shows that the homogeneity of glasses produced from gels is achieved in a much shorter melting time than in the conventional process. However, experimental results on the structural relaxation in gel-sintered glasses (Scherer and Brinker, 1986) lead to the conclusion that no significant differences exist after the gel has been sintered near T_g . A SAXS study on the kinetics of phase separation in gel-derived and melt-quenched soda-silica glass demonstrated that OH accelerates the growth of the new phase appearing in the parent matrix (Neilson *et al.*, 1986). Additionally, for similar OH contents there is no striking difference between the phase separation behavior of the gel and ordinary glass. Brillouin and low-frequency Raman scattering (Terki *et al.*, 1996; Caponi *et al.*, 2004) have shown small differences between sintered silica aerogel and vitreous glass. These differences in the sound velocity, the hypersonic attenuation, and the frequency of the so called 'boson peak' (characteristic of the medium range order) can also be attributed to the higher OH content. Finally, despite structural differences before sintering, the structure and properties of gels heat treated above T_g become indistinguishable from those of conventional glasses obtained by quenching the melt, if the gel and the glass are identical in composition (including OH content). Another question is whether gel-derived glasses exhibit the same crystallization behavior as ordinary glasses (Mackenzie, 1988). In contrast to the expected advantage of the sol-gel route (its ability to produce glasses having compositions which normally crystallize when quenching the melt), it has been shown that gels of glass-forming systems tend to nucleate and crystallize at much lower temperatures than conventional glasses. This behavior has been attributed to the high OH content and higher surface area, which could lead to enhanced rates of crystal nucleation (Zanotto, 1992). Glass formation by the gel route requires heating the gel at a slow rate followed by holding the gel at a temperature in the vicinity of T_g . This is a risky path to follow because the nucleation region has to be crossed (Uhlmann *et al.*, 1988). It is worth noting that the compression process that speeds up the densification sometimes avoids extensive crystallization of the amorphous gel (Zarzycki, 1997).

Porous Glasses

New kinds of glasses have been studied and synthesized for specific application: the porous glasses. General agreement is that porous glasses exhibit physical behavior similar to that of dense glasses, more or less affected by the porosity. Porous glasses can originate from different processes. The first way was from conventional melting and quenching process which is modified to produce bubbles in the melt or pores in the dense structure. The bubbles are obtained for example, by the decomposition of carbonates during the melting. An example of application of the foamed glasses is as biomaterials for bone prosthesis (Gough *et al.*, 2004). Another example of porous glass obtained from the classical way is the microphase separated and leached 'Vycor' glass. An acidic corrosion treatment dissolves the 'weak' (borate) phase and creates a continuous porosity in the silicate phase. By controlling the composition and the heat treatment it is possible to adjust the pore size (Elmer, 1992).

Xerogels and aerogels previously described can be considered as porous glasses although the very different way used to attain the 'glassy' state. The potential applications of these very porous materials are for catalysis, insulator, acoustic transducers, energy storage devices (Aegerter, 2011). Another possible interest of these porous materials is as a host matrix for the synthesis of multi-phase materials. The large pore volume is used as a sponge to incorporate chemical species with the objective to get a two phases material. However, the counterpart of this porosity is the poor mechanical properties and the consequence is that very porous materials crack during filling because of capillary forces.

It is generally admitted that inclusion of particles or fibers in the material could improve the mechanical properties. In previous works it has been shown that it is possible to adjust the apparent density, the mechanical properties and the permeability by the addition of silica powder in the monomer solution, just before gelation (Toki *et al.*, 1988; Reynes *et al.*, 2001). The mechanical performance increases by a factor 5, the mean pore diameter and the permeability increase too and this composite aerogel is able to resist the capillary stresses during the pore filling by a liquid.

The different kinds of gel-derived porous glasses (xerogels, aerogels and composite aerogels) have been used as host matrix for very different applications. Guest molecules are deposited on the surface of the skeleton when the liquid is further evaporated. The tailoring of the mean pore size and of the pore size distribution is needed to facilitate a homogeneous dispersion of doping molecules within the texture. Graded porous volume with graded pore size could be obtained (Gui *et al.*, 2011). The control of the chemical species diffusion inside the porosity has been done to synthesize gels and glasses showing graded properties such as gradient refractive index (Yamane and Inami, 1992). Soaking by solutions of rare-earth ions has been also successfully applied to synthesize doped silica glasses interesting for their Faraday effect. These glasses contain Er, Mn and Dy with different Verdet constant (Bouaziz *et al.*, 1986). For these optical applications the very pure optical quality of the silica network issued from the sol-gel route is one of the important parameters.

The impregnation of gel derived porous glasses has also been proposed for the containment of nuclear wastes (Woignier *et al.*, 2000; Deptula *et al.*, 2011). In this case, the important key is the very high chemical durability of the silica matrix which traps the nuclear wastes and protects them against water corrosion (Woignier *et al.*, 2011). After the soaking treatment, the host matrix is dried, then sintered. The resulting material is a composite constituted by nuclear wastes crystals embedded into a silica matrix. The initial dissolution rate of such a composite in water is 10^2 times lower than that of the nuclear classical glasses (Reynes *et al.*, 2001).

Conclusions

In summary, the material resulting from the sol-gel route is a precursor of glass but it is also a material with a polymerizable structure, a high OH content, a high surface area and a high pore volume. Compared with a glass of the same oxide composition, the dried gels have higher structural energies. Surface area, silanol groups, and additional free volume (because of a lower cross-link density) contribute to this high free energy and during the thermal conversion to glass the gel changes to become more highly connected while reducing its surface area and free volume (James, 1988).

Gel-derived silica glass exhibits physical properties identical to those of conventional silica glass. The advantage of the sol-gel route is the low heat treatment temperatures and the high level of purity of the sintered material. The process has been extended to bulk multicomponent glasses (borosilicate, phosphosilicate, lanthanide-doped glasses, etc.). For optical applications, gradient index (GRIN) optical elements (Yamane and Inami, 1992) and optical lenses without the need for polishing have been synthesized. New glass matrices for the containment of nuclear wastes have been generated by the sol-gel route (Reynes *et al.*, 2001; Deptuła *et al.*, 2011). In the field of coatings on glass, the application of thin coatings by the sol-gel route is competitive with sputtering, as it is simple and less costly (Dislich, 1984). Major products are sun-shielding layers, non-reflective coatings, scratch-resistant surfaces, and films with a low dielectric permittivity.

Keeping in mind that producing glasses is only one end product of this process, new types of material are being developed. The intermediate stages of the process give the potential for generating new families of materials, for example by combining polymer synthesis with sol-gel techniques (Schmidt and Wolter, 1990; Sakka, 2005; Aegerter, 2011). These combinations produce hybrid networks (organic/inorganic) where the organic constituents are not eliminated by heat treatment and participate to the network connectivity. Another family of new materials results from the biphasic character of the gel; the porous texture of the gel can be used as a host matrix (Woignier *et al.*, 2005). The porosity allows the impregnation of the gel with a liquid species. The possibility of adjusting the pore volume and the diversity of potential liquids (monomers, electrolytes, salts in solution, gelifying solutions, etc.) extend the possibilities of the sol-gel glass process to a large range of products, from doped silica glass to composite and container materials.

Besides the technological interest, the sol-gel route also presents various fundamental, interesting problems. Gels have been used to test experimentally models of aggregation (monomer-cluster, cluster-cluster) and the associated structures calculated by numerical simulation. Aerogels are ideal materials in the sense that the evolution of physical properties in relation to the structure can be experimentally studied over the whole range of porosity from 0 to 99%. Moreover, the small size of the pores can lead to specific behavior of molecules in confined media (Fehr *et al.*, 2003).

Glasses and Glass-Ceramics Prepared by Sol–Gel

Introduction

For thousands of years, glass and ceramic materials have been produced using conventional melting and sintering processes that involve high temperature. Diverse alternative routes have been proposed, most of them focused on the reduction of the melting and sintering temperature (Dimitriev *et al.*, 2008). Between them, the “Sol–gel chemistry” constitutes a new and flexible non-traditional method for processing ceramic and glass materials at low temperatures since it is a wet-chemical technique. The possibility offered by Sol–gel technology to produce an extensive range of nano-/micro-structures combined with the good control of the properties makes it one powerful technique to fabricate materials (Owens *et al.*, 2016).

The first approach related to Sol–gel method appeared in the mid-nineteenth century (1846), when Ebelmen, a French chemist, observed how silicic esters hydrolyze slowly in the presence of humidity giving hydrated silica (Ebelmen, 1846; Schneller *et al.*, 2013). However, the term “sol–gel” was first proposed by Graham in 1864 and almost 100 years later appeared in the first patent for Sol–gel dealing with the synthesis of SiO₂ and TiO₂ materials for optical applications (Bahuguna *et al.*, 2016). These compositions were re-formulated by Schroeder (1969) and further used in the fabrication of thin films on glass substrates by Sol–gel at industrial scale. In the same year, Mazdiyasn *et al.* (1969) prepared high-purity barium titanate powders.

In addition to the benefit of the low processing temperatures, Sol–gel process shows advantages as high homogeneity, molecular control of the composition and a wide variety of compositions with many different properties.

The importance of “Sol–gel process” became apparent in 1981, in the first “International Workshop on Glasses and Glass Ceramics from Gels” organized by Prof. Vittorio Gottardi and held in Padova, Italy. In this conference, the Sol–gel community, around 30 attendants mainly from glass research centers from Europe, opened the field to the industrial and academic world.

The first stage of the Sol–gel process is the preparation of a stable solution (sol), followed by a gelation and solvent evaporation resulting in the formation of a “gel”, densification and crystallization being the final stages. Even though there are several processing routes, two are the better established in the literature: the colloidal route and the polymeric route, represented in Fig. 1. These routes have a common point the “gelification stage”, although the beginning is essentially different. In the colloidal route, the method starts from a colloidal suspension of small particles in a continuous liquid medium, where the gravitational forces are negligible. In the case of the polymeric route, the “sol” is obtained by controlled hydrolysis and condensation of metal-organic precursors (e.g., metal alkoxides or alkylalkoxides). In both cases, to incorporate a destabilizer or a catalyst increases the viscosity and transforms sol into gel, obtaining a continuous network that encloses the liquid phase. At this point, the gel maintains its shape. Drying and aging steps follow for removing the liquid phase (solvent).

The first materials prepared by Sol–gel were pure inorganic materials. However, in the eighties, Schmidt (1984) at the Fraunhofer Institute began to introduce organic groups in the inorganic networks, which had a big impact in the Sol–gel synthesis. The possibility to create novel materials allowed the expansion of the Sol–gel method to other areas. Livage (1997) explained the impact of synthesizing inorganic–organic hybrid materials that provide unique properties by combining the stability of the inorganic part with the flexibility and functionality of the organic part. This idea was linked to the concept of “chemie douce” referring to the processes of soft inorganic chemistry for creating tailored hybrid organic-inorganic materials. The versatility of blending inorganic with organic phases, gave rise to outlining different structures from ordered dispersions of inorganic bricks in hybrid matrix to highly controlled nano segregation of organic polymers within inorganic matrix (Sanchez *et al.*, 2001). The structure and the properties depend on the nature of the inorganic and organic molecules as well as the synergy between them. Sanchez *et al.* (2003) classified these Sol–gel materials in four types depending on the degree of organization including from ordinary hybrid networks from organically modified metal alkoxides to the synthesis or mesostructured hybrid networks that combine nano-building blocks and self-assembly approaches (Sanchez *et al.*, 2010).

Yanagisawa *et al.* (1990) and Kresge *et al.* (1992), Mobil and Japanese scientists turned the screw in this field thanks to the creation of the first mesoporous hybrid silicate, bringing the opportunity to create novel systems combining the pore size, shape and symmetry control with a tailored surface with amazing properties, in most cases, referred to optics.

The physical-chemical variables involved in the process are crucial to determine the final structure, morphology, and chemical composition of the products. The ability to design and control the different stages of the Sol–gel process allows new materials with enhanced and tailored properties to be prepared. The technique is compatible with many conventional material processing methods (e.g., casting, dip coating, spin coating, doctor blading, and spray coating), allowing the processing of sol–gel-derived materials in a variety of structural shapes, such as nanoparticles, supported thin films and coatings with controlled thicknesses, patterned surfaces, membranes, and monoliths. The potentiality and possibilities of designing original structures and compositions is reflected in the high impact in high-tech industries and optical fields of applications (Green *et al.*, 2003; Soler-Illia and Innocenzi, 2006; Fan *et al.*, 2008; Soller-Illia *et al.*, 2011) (Fig. 2).

Fig. 1 Colloidal and polymeric sol-gel routes.

Fig. 2 Critical aspects of sol-gel chemistry mesostructure assembly. Reproduced from Boettcher, S.W., Fan, J., Tsung, C.-K., *et al.*, 2007. Harnessing the sol-gel process for the assembly of non-silicate mesostructured oxide materials. *Accounts of Chemical Research* 40 (9), 784–792.

In this review, we present an insight on the advances in Sol-gel route, considering the physical and chemical aspects implicated in the process as well as an overview of the most important developments and applications. The better developed and used polymeric route is described in deeper detail.

Physical-Chemical Basis of the Process

Several papers appeared between 1846 and 1927 explaining the formation of hydrolyzed derivatives of silica. King and Threlfall (1928) deposited the first patent for partial hydrolyzed alkoxysilanes, describing the preparation of a solution of silica using a reaction between an ester of silicic acid and water. It was mentioned that the proportion of water must not exceed that required to convert the ester into an alcohol.

Although the discovery and the first developments on the formation of gel focused on silica as main element, a huge variety of metals can be used instead or mixed with silica. Ray (1934) from Carbon Chemical Corporation patented the hydrolysis and condensation processes for a generic metal that can be other than silicon. After specific studies and observations of Roy and Osborn (1954) the use of metal-organic precursors expanded a lot including a long list of metallic elements that can be prepared by Sol-gel.

Nowadays, many papers describe in detail the hydrolysis of alkoxides, especially metal alkoxides, using Eq. (1), in which M is a metal (Si, Al, In, Ti, Zr, Sn, Pb, Cr, Ta, etc.) and R an alkyl group. This reaction is followed and combined with the condensation (Eqs. (2) and (3)).

Hydrolysis:

Condensation can follow two routes, and usually both occur:

Metal-organic compounds are typically the most used precursors, especially tetra alkoxysilanes and tetra-methoxy-silanes. If the reactivity of the precursor is high, the reactions will occur so quickly to become difficult to control. The reactivity relates to the number of sites able to form Si-O-Si bonds. In case of alkoxides, this can be controlled by the modification of the group R: If the non-hydrolysable radicals increase, then the functionality decreases. Following this, alkoxides have a hydrolysis slower than alkyl-alkoxides.

Villegas Broncano and Fernandez Navarro (1987) reviewed the polycondensation reactions from monomeric units of the same specie as well as copolymerization of a mixture of different monomers. In this last case, it is important to control carefully the kinetics as they have different behavior.

With hydrolysis and condensation reactions, it is possible to create highly branched structures; when complete condensation takes place, compact oxides are produced. The structural differences depend on the basic equations (Eqs. (1) and (2)). Conditions such as the pH, catalyst and H₂O/alkoxide ratio affect the final structure. Chang and Ring (1992) explained the control of the reactions of hydrolysis and condensation deeply studying the aggregation of the species throughout the transition from the sol to the gel state.

Sakka and Kamiya (1982) described the relation between the hydrolysis of TEOS and the amount of HCl incorporated in the reaction. In the same decade, different publications confirmed that hydrolysis becomes more rapid by employing either basic or acid catalysts. The most used catalysts are mineral acids or ammonia but others, such as KOH, KF, HF are also known. Pope and Mackenzie (1986) studied the effect of a variety of catalysts on the hydrolysis and condensation of TEOS (Tetraethyl orthosilicate) and their relationship with the time needed for gelation, as shown in Fig. 3.

Chang and Ring (1992) exposed the relationship of reactions shown in Eqs. (1) and (2) with pH. In acid conditions, the hydrolysis is slower, the condensation rate increasing the aggregation of high-branched clusters forming a network. Under basic conditions a much-accelerated nucleophilic attack is involved. Larger structures have tendency to interact with smaller ones, exchanging OH⁻ and releasing OR groups. The size of the polymer formed is higher than those formed in acidic conditions and they show higher density.

The gel point is defined as the moment at which the variation of the viscoelastic function with the vibration is at a minimum. The characteristics of the bonds define the final structure of the gels. Flory (1974) described the gel behavior where modulus of elasticity depends on the interlinking density of the network. Flory indicates that gelification is strongly dependent on the bonds, a main issue to control the network evolution through scale time. Once the polymeric network grows, the amount of clusters decreases and, so, the sol is not able to flow, becoming a viscous gel supporting a static load without floating. Rabinovich (1985) described the factors provoking the acceleration of the gelation point, in particular, the temperature, the increasing of the water ratio, a higher concentration of alkoxides and the increment of pH.

The obtained gel contains a high free energy because of its large surface area, high amount of chemically bound water and the final high volume. Orgaz-Orgaz (1988) studied the densification steps of the gel, which is an irreversible process in which the decrease in free energy proceeds along with a decrease in surface area, a reduction in pore size and volume.

Fig. 3 Effects of catalyst on pH and gel times for TEOS hydrolyzed with 4 equivalents of water. The catalyst concentration is 0.05 mol: TEOS. Modified from Pope, E., Mackenzie, J., 1986. Sol-gel processing of silica. II. The role of the catalyst. *Journal of Non-Crystalline Solids* (87), 185–198.

Once the gel point is reached, the structures corresponding to fast gelation times are opened and porous, due to the lack of possibility to link further rearrangement. Vega and Scherer (1989) demonstrated by NMR that mobile and immobile polymers exist in the sol at the gelation point. At this moment, chemical reactions are still occurring and are crucial to define the properties as they affect the drying and sintering.

The following step to gelation point is aging. Polymerization is a main reaction involved in this step, increasing the connectivity by condensation reactions caused by the availability of hydrolyzed remaining groups. pH and temperature at which the gel is achieved govern the time necessary to complete the aging that goes from a few days to several months. Drying occurs after the aging with the transition from wet gel to a dry one by physical water and solvents desorption.

Scherer (1992) described the drying of gels in two consequent steps. The first one, called “Constant Rate Period” (CRP), is characterized by a constant evaporation rate, where part of the liquid evaporates by capillary force. The wet gel shrinks continuously under compression, and the remaining liquid fills the pores. This initial period is critical for the control of the gel cracking because of the capillary tensions generated in the remaining liquid. It is possible to control cracking by adjusting the evaporation rate, the results being inversely proportional to the pore size: the higher the pore size the more reduced is the cracking. In the second step a small evaporation of the liquid still in the gel occurs, being the crucial phase in which cracking could appear. Preventive measures must be taken to avoid it, like lowering drying velocities from the beginning or by using hypercritical-drying condition (Bisson *et al.*, 2003).

A final homogeneous and dense glass or glass-ceramic results after a consolidation period that includes the thermal treatment of the gel. Numerous researchers explained that the gel densification and its properties depend on the sequential gelation, aging and drying parameters under which it was prepared.

Although Sol-gel steps are apparently sequential, in the case of coatings formation a competition is present between evaporation and condensation reactions. Brinker *et al.* (1992) explained how capillary forces influence the system promoting compaction during the evaporation and generating a resistance to it during condensation. They also described the effect of different balances between evaporation and condensation rates on the structure of the formed coating. In addition to the reaction rates and duration of each stage, other parameters need to be controlled to achieve a desired coating, and the method of deposition used strongly determines the final structure and is closely related to the specific applications.

Another important Sol-gel process relates to the preparation of monodispersed silica nanoparticles of controllable and uniform size, reported by Stöber and Fink (1968). It remains as the most used wet synthetic route to obtain silica nanoparticles. The synthesis takes place when a molecular precursor (typically tetraethylorthosilicate) reacts with water in an alcoholic medium in presence of ammonia as catalyst. Esquena *et al.* (1997) prepared silica particles with sizes above 1 μm by Sol-gel process. In this case, the reaction takes place in the aqueous medium in an acidic emulsion media using HCl. During the first minutes of reaction, the solution turns to a turbid suspension as evidence of the particle formation.

Li and Zhao (2013) proposed that during the Stöber process, a rapid burst of nuclei occurs, and the uniform particles grow without additional nucleation because of the attachment of constituent solutes in a kinetically controlled ambient. Following this idea, the Stöber process extended to obtain titanium nanoparticles, was more difficult to control due to its high reactivity. The preparation of core-shell nanoparticles combining SiO₂ or TiO₂ as shell and different compounds as core have gained interest in recent years (Kobayashi *et al.*, 2005; Yang *et al.*, 2013; Bai *et al.*, 2016).

Applications

The extensive possibilities of compositions able to be prepared by sol-gel, the inorganic, hybrid or organic precursors used in the different synthesis routes, and the multiples shapes of final products, from thick coatings to thin films, powders, monoliths or aerogels with amazing properties, allows this synthesis method to be applied in a variety of fields. The often-used materials, as metals, glasses, ceramics, or plastics, cover a traditional application, but these pure materials do not fulfill the requirements of many new innovative requirements or the design of multifunctional materials. The outbreak of hybrid synthesis by Sol-gel in the past decades made an enormous progress and lead to new materials with enhanced properties and cost-effective prices in many cases.

The objective of this section is to give a look and summarize the most important applications in the field of glasses and glass-ceramics, from biomaterials to optics, photo-catalysis or protective coatings. The goal is to describe the huge possibilities of this synthesis route and their applications and possibilities in the field of material science and technology.

The preparation of coatings is the most developed field of application of Sol-gel process. Large substrates with different shapes can be coated by cost-effective processes. Coatings are prepared from a single inorganic precursor, as well as by the combination of organic and inorganic materials. Single and multi-component oxide coatings are produced as monolayers or structures of films to provide different functionalization to glass and other substrates.

Deposition Methods for Sol-Gel Coating

Brinker and Scherer (1990) described the parameters implicated in the deposition process and highlighted that the rate of evaporation and condensation process determines the pore volume, pore size and surface area of the final films. A brief description of the most important methods used to prepare coatings is presented considering the factors involved in each method and the variety of applications.

Dip Coating Deposition

The dip-coating process involves the controlled vertical withdrawal of the substrate from the liquid at a specific velocity U_0 as shown in Fig. 4(a) (Brinker *et al.*, 1991). Scriven (1988) described the five stages of this coating process: immersion, followed by the start-up, deposition and drainage as simultaneous stages; evaporation as a final step occurs throughout the whole process.

During the immersion, while the substrate pulls the fluid going deep into the sol, two flow sol dynamic layers are generated (Streamline point "S", Fig. 4(b)). As shown in Fig. 4(b), the outer layer (O), returns into the bath while the inner one (I) takes the substrate direction (Brinker and Hurd, 1994). The final thickness of the coatings strongly relates with the dynamics of these two layers and the position of S point (Scriven, 1988; Brinker *et al.*, 1991).

Fig. 4 (a) Schematic of the dip coating process with sequential stages during the development of the structure. (b) Sol flow patterns during dip coating. Modified from Brinker, C.J., Sehgal, R., Hietalab, S.L., *et al.*, 1994. Sol-gel strategies for controlled porosity inorganic materials. *Journal of Membrane Science* (94), 84–102.

Fig. 4(a) shows the parabolic shape provoked by the non-constant evaporation rate in the proximity of the drying line. The pore size is controlled by the structure, composition, rates of condensation and evaporation and the capillary pressure, which, as can be observed in Fig. 4(a), takes a different value in each part of the parabolic shape (Brinker *et al.*, 1994).

Strawbridge and James (1986) described for the first time the different parameters that affect the final thickness. The equations were further modified to include new parameters that allow the most realistic behavior to be described. Brinker and Scherer (1990) advanced that the thickness variation depends on three important parameters, shown in Eq. (4), while the viscosity and density are constant. The relationship simplifies when considering that the lower the withdrawal rate, the thinner is the film, mainly due to an overlap between the deposition and drying stages (Thomas, 1994).

$$\text{thickness} \propto \frac{(\text{viscosity})(\text{withdrawal rate})^{1/2}}{(\text{density})} \quad (4)$$

Guglielmi and Zenezini (1990) proposed a new equation (Eq. (5)) that includes the measurable parameters of the sol, and fits well the evolution of film thickness in inorganic sols.

$$t_p = 10^{-3} \left(\frac{C_p}{\rho_p} \right) I \left(\frac{\eta U}{\rho g} \right)^{\frac{1}{2}} \quad (5)$$

Where t_p is the thickness of the heat-treated coating, C_p is the concentration of the solution expressed in grams of silica per litre, ρ_p is the density of the heat-treated coating expressed in $\text{gr} \cdot \text{cm}^{-3}$, η is the viscosity of the liquid, U is the withdrawal rate, ρ is the viscosity of the liquid and g is the gravitational acceleration.

During the evaporation step, the density of the coatings and the surface tension are constantly changing; this dynamic situation influences the drying profile which is also related to the ambient conditions as well as the specific characteristics of the sol and the substrate.

Brinker *et al.* (1994) described in detail how polymer or particle size, structure, reactivity, relative rates of reactions, liquid surface tension and the dipping withdrawals affect the final microstructure and thickness of the coating.

Spin Coating Deposition

Spin coating process is the simplest method to produce uniform thin films on flat substrates with thicknesses from nanometers to micrometers, (Sahu *et al.*, 2009). Bornside *et al.* (1987) described the spin process consisting of four stages: deposition, spin up, spin off and evaporation of the solvents. Like the dip-coatings process, the evaporation overlaps with the other stages. The deposition begins when the sol falls on a rotating substrate, which is accelerated up to the final speed. Secondly, a centrifugal force governs the spin up stage by letting the liquid flow radially and allowing the fluid to reach a uniform thickness. During the spin off stage, the excess of liquid on the surface flows to the perimeter. The evaporation of the solvent proceeds throughout all the steps governing the last stage, mainly when the vapor is overhead and saturated with volatile components. The rate of evaporation is a function of the partial pressure of the solvents and the amount of volatile components. The forced convection of the vapor above creates a mass transfer coefficient that is also uniform, generating a constant rate of evaporation.

Spin coating has an evident advantage due to the higher layer uniformity in comparison with others deposition techniques (Strawbridge and James, 1986). Ideally, the thickness is inversely proportional to the square root of the rotation speed (Thomas, 1994). Although, it is overly sensitive to the spin speed, the viscosity of coating solution, and roughness of the substrate.

However, the dip-coating and spin-coating processes present important limitations, the most important related with the maximum thickness obtained (Castro *et al.*, 2004). To solve this aspect, and other limitations, many efforts were developed to produce Sol-gel coatings with other techniques, such as EPD deposition.

Electrophoretic Deposition

Since dip-coating and spin-coating techniques focus on flat substrates and thin thicknesses, electrophoresis deposition was proposed as good alternative method to Sol-gel coating (Sheffer *et al.*, 2003; Castro *et al.*, 2004).

Clark *et al.* (1988) defined the electrophoresis as the movement of charged particles in a fluid (suspension) due to the application of an external electric field. According to Van der Biest and Vandeperre (1999), electrophoretic deposition is a combination of two processes, electrophoresis, and deposition. The electrophoresis involves the motion of charged particles in a stable suspension under an electric field, while the deposition is the result of the impact of these particles against the electrode of opposite sign. The rate of migration depends on many factors including size and shape of particles, physical and chemical characteristics of the support medium, the strength of the electromotive force and the ionic strength of the buffer. The power supply also plays an important role and a constant voltage or constant current can be used, although constant current is preferred with longer electrophoresis times.

On the other hand, the deposited mass is a function of different parameters such as particle concentration, electrophoretic mobility, area of the substrate, applied field and deposition time.

Spray Coating

In many cases, spray coating is chosen because of its suitability to cover surfaces without limits of geometry or dimensions, and the simplicity of the equipment needed. [Chen et al. \(1999\)](#) defined the process as the atomization/spraying of a suspension of droplets of the order of tens to hundreds of micrometers, followed by a drying process to produce a continuous surface of solid particles. To generate droplets, the liquid can be atomized by rotary disks, two-fluid nozzles or ultrasonic nebulizers, depending on the droplet size required. Larger particles arrive first to the substrate surface, creating a coating with different particle sizes, and porosity.

Different physicochemical parameters such as pH, viscosity or temperature affect the structure of the coating.

Applications of Sol-Gel Coatings

Optical and Photonics Applications

Inorganic and organic-inorganic hybrid Sol-gel coatings showed important optical applications due to their emissions, luminescence, optical nonlinearity and sensing properties, which modify the reflectance, transmission or absorption of the substrate. Moreover, Sol-gel process allows the incorporation of optically active particles or molecules into the Sol-gel matrix, and the possibility to dope them.

For many years, different oxides as Sol-gel layers for photovoltaic cells, especially TiO_2 with SiO_2 in different configurations, proved successful, improving the solar cells efficiency ([Pettit et al., 1985](#); [Lee et al., 2003](#); [Faustini et al., 2010](#)). Other oxides such as ZnO are also developed for similar applications. The review of [Znaidi \(2010\)](#) deeply describes the preparation and characterization of ZnO Sol-gel coatings.

Light emitting diodes reached unique results for highly condensed films. [Shi et al. \(2015\)](#) studied the photo-activation of hybrid Sol-gel coatings for its use as diodes and, [Yilmaz et al. \(2015\)](#) described the preparation of *n*-ZnO films on p-Si substrates diodes by dip-coating. Many papers report the use of white light emitting diodes ([Kim et al., 2009](#); [Keskenler et al., 2013](#); [Fu et al., 2013](#); [Nayak et al., 2009](#)). Although Schottky-prepared diodes combining different precursors and layers showing many advances, there still exists the need for the development of novel phosphor materials to increase down-conversion efficiencies ([Gouveia-Neto et al., 2012](#); [Righini et al., 2019](#)).

Particular attention was paid to the preparation of oxyfluoride glass-ceramics (OxGCs) for photonic applications after the pioneering work of [Wang and Ohwaki \(1993\)](#) ([de Pablos Martín et al., 2002](#)).

The Sol-gel route appears as a promising alternative to prepare OxGC films and bulk materials avoiding the limitation of melt-quenching (MQ) such as the loss of fluoride content. OxGCs are polycrystalline materials containing active lanthanide-fluoride nano-crystals (NCs) that crystallize in a glass matrix. The doping of nanocrystal with rare earth allows the optical properties to be improved ([Gorni et al., 2018a,b](#); [Zhou et al., 2018](#)). The incorporation of active nano-crystalline phases into a silica glass matrix combines the low phonon energies of fluoride nanocrystals ($250\text{--}450\text{ cm}^{-1}$) with the excellent thermal, mechanical, and chemical stability of oxide glass matrices. The low phonon energy can reduce the non-radiative de-excitation probability of the luminescent RE ions by the multi-phonon relaxation ([Gorni et al., 2018a,b](#)). [Gorni et al. \(2017a,b\)](#) prepared crack-free $80\text{SiO}_2\text{--}20\text{LaF}_3$ coatings doped with $3\%\text{Nd}^{3+}$ and Er^{3+} , confirming the incorporation of the dopants in the NC and including up to 18% wt of LaF_3 , the highest crystalline fraction ever reported ([Gorni et al., 2019](#)), [Fig. 5](#).

In particular, doped $\text{SiO}_2\text{--LaF}_3$ materials are interesting for optical and photonic applications such as photovoltaic devices where the efficiency of solar cells could be improved by modifying and widening the solar spectrum range able to be used, and as dielectric ceramics used in resonators, for planar integrated photonic applications, etc. Lanthanide-doped GdF_3 is considered a promising host because Gd^{3+} ions can act as a sensitizer for other Ln^{3+} ions and enhance the luminescence processes ([Chen et al., 2008](#)). On the other hand, $\text{SiO}_2\text{--NaGdF}_4$ or $\text{SiO}_2\text{--GdF}_3$ matrix may be suitable for infrared and tunable phosphors, sensing, solar cells, plasma display panels, biomedical imaging, and others ([Yin et al., 2012](#)). YF_3 -based sol-gel nano-glass-ceramics are good candidates for photovoltaic applications such as efficient phosphors due to the wide band gap (4.10 eV) and the fact that Y^{3+} sites can be substituted by some trivalent RE ions. The preparation of these materials as coatings is gaining more and more interest because new and novelty applications are possible, such as displays or smart windows.

Protective Coatings

The use of Sol-gel coatings is a good alternative to improve the resistance to corrosion or abrasion of metal substrates reducing the contact between substrate and aggressive medium.

[Durán et al. \(2018\)](#) classified Sol-gel protective coatings in three groups:

- Inorganic and organic-inorganic hybrid coatings with low content of organic groups with sintering temperature between 400°C and 500°C .
- Organic-Inorganic hybrid coatings with high organic content cured under 200°C .
- Inorganic and hybrid coatings with corrosion inhibitors.

Transparentsol-gel oxyfluoride glass-ceramics with high crystalline fraction and study of RE incorporation. Nanomaterials (9), 1–16.

Inorganic coatings provide good corrosion protection against oxidation and nitridation in anhydrous media of stainless steels (Shane and Mecartney, 1990; Atik and Aegerter, 1992; de Sanctis *et al.*, 1995; de Damborenea *et al.*, 1995; Voevodin *et al.*, 2001). SiO_2 and SiO_2 - ZrO_2 Sol-gel coatings are the most studied compositions, but others were also considered such as ZrO_2 , B_2O_3 , SiO_2 - B_2O_3 , SiO_2 - ZrO_2 , SiO_2 - TiO_2 , ZrO_2 - Y_2O_3 , ZrO_2 - CeO_2 . Inorganic coatings of SiO_2 constitute an efficient protection of surface mirrors for solar collectors (Morales and Durán, 1997). However, the sensitivity to corrosion in electrolytic media is high due to the presence of micro-cracks or defects in the pure inorganic coatings. The incorporation of low amounts of organic groups allows reductions in the penetration of the electrolyte compared to pure inorganic films, offering better electrochemical behavior as well as increased ductility and thickness (Gallardo *et al.*, 2003). These hybrid coatings are demonstrated to be also suitable for biological applications when bioactive powders are incorporated, inducing the formation of hydroxyapatite when in contact with physiological solutions (Gallardo *et al.*, 2001; Garcia and Durán, 2006).

Inorganic-organic hybrid coatings with high organic contents are appropriate for protecting light alloys such as aluminum, magnesium, or their alloys, widely used in automotive, aeronautic and aerospace industries. Conde *et al.* (2002) demonstrated that corrosion resistance of aluminum alloys improves when polymeric sols are prepared with the addition of colloidal suspension. This type of coating is quite interesting because it combines the properties of organic compounds (flexibility, high density, (Rosero-Navarro *et al.*, 2009a,b) and compatibility with the paint system) with those of inorganic components (scratch resistance, durability, etc.).

The most recent trend in corrosion protection is the incorporation of inhibitors in hybrid Sol-gel coatings, the third group. Protective coatings with inhibitors permit repair of damages without external intervention, the so-called *self-healing effect*. Two different types of coatings are considered: (1) conversion coatings obtained from rare earths and inorganic coatings of pure inhibitors produced by Sol-gel (Fahrenholz *et al.*, 2002; Conde *et al.*, 2008; Rosero-Navarro *et al.*, 2011); (2) coatings obtained by incorporation of inhibitors to hybrid coatings (Rosero-Navarro *et al.*, 2009a,b; Carvalho *et al.*, 2014). These films can be furthered coated with epoxy paints for use in the aircraft industry (Durán *et al.*, 2018).

In other approaches, a number of organic compounds such as triazole and thiazole derivatives, 8-hydroxyquinoline and phosphonate-containing compounds or nano-reservoirs or nano-containers are also investigated as alternative corrosion inhibitors, associated with their good compatibility with hybrid coatings (Borisova and Schukin, 2013; Chen and Fu, 2012). However, it is difficult to control the release of the inhibitor to ensure a continued delivery to corrosion sites.

Last approaches focus on the combination of protective layers to arrive to an effective long-lasting corrosion protection (Castro *et al.*, 2020). Fig. 6 provides a schematic of the protective structure consisting of a first anodizing layer cover with a pure glass-like CeO_2 inhibiting layer finally protected with a thick hybrid SiO_2 layer.

Porous Coatings for Sensors, Biosensors and Photo-Catalysis

It is possible to control the porosity (pore volume and pore size) of inorganic coatings obtained by Sol-gel by adjusting the rate of condensation and evaporation and using structure-directing agents (surfactants) (Brinker *et al.*, 1994). These porous materials

present high surface area and intrinsic porosity, showing unique structures. Due to their special characteristics, they find many applications as sensors, biosensors and photocatalysts.

Photo-catalytic activity of mesoporous TiO_2 coatings attracted high attention. Fujisjima *et al.* (2008) intensely studied the photocatalytic behavior of TiO_2 coatings, concluding that their super-hydrophilicity constitutes a great advantage for this application (Sharma *et al.*, 2006). The Dionysiou group (Antoniou and Dionysiou, 2007; Quici *et al.*, 2010) is a key reference in this field. On the other hand, Arconada *et al.* (2011, 2010, 2009) described the photocatalytic activity of multilayer mesoporous TiO_2 films in aqueous solution (methyl orange) and in gas phase (trichloroethylene, hydrogen sulfide and methyl ethyl ketone). The control of crystallinity and the structural and textural properties of the semiconductor, such as the specific surface area, porosity, volume and distribution of the pore size are crucial to improve the photocatalytic behavior. In general, the addition of surfactants increases the thickness of the coatings generating catalysts with high meso-porosity and specific surface area, suggesting a higher contact surface between pollutant and semiconductor, and higher photocatalytic activity (Castro and Durán, 2015).

Other important application of mesoporous TiO_2 coatings involves the combination of biocidal activities with self-cleaning properties. Roldán *et al.* (2015) described the preparation of different systems consisting of a layer of SiO_2 followed by a mesoporous or dense layer, doped with silver nanoparticles (Ag NPs) (Fig. 7). The authors reported the preparation of dense and mesoporous $\text{SiO}_2/\text{TiO}_2$ coatings doped with Ag nanoparticles and found very high and synergic photocatalytic and bactericidal

activities. The best photocatalytic activity appears when Ag nanoparticles situate in the SiO_2 layer, whereas the best bactericidal property is reached when the Ag nanoparticles are in the TiO_2 layer.

Although TiO_2 is the most widely used semiconductor for photocatalytic applications, other oxides, such as SiO_2 , Al_2O_3 , ZnO or their combinations are also utilized (Pal and Sharon, 2002). A high porosity and specific surface area is necessary to promote an extensive contact between the organic compounds and the semiconductor surface (Haas-Santo *et al.*, 2001).

Sol-gel coatings also have an extensive field of applications as optical sensors to determine pH, ionic species or solvents as well as gas sensors and biosensors (Jerónimo *et al.*, 2007). The films change their optical behavior as response to environmental changes (Jeon *et al.*, 2013). pH sensitive dyes can be immobilized in Sol-gel films to be used as indicators. Absorption, fluorescence, and luminescence are used for detection. Depending on the indicator and Sol-gel precursors used the response time changes from less than 1 s to more than 4.5 min (Nguyen *et al.*, 1999; Ertekin *et al.*, 2003). Lifetime and stability can also vary from hours to months (Lobnik *et al.*, 2001; Wang *et al.*, 2003). Sensitive systems for gas detection based on Sol-gel coatings were also widely developed as the nano porosity of the Sol-gel matrix is used as a path for gas molecules where functional particles can be embedded and films show a reversible change in optical transmittance when exposed to certain gases, providing detection limits of 10 ppm (Martucci *et al.*, 2003). Based on the immobilization of reagent of colored complexes, thin films for ionic species detection are extensively used with detection limits above 1 ppm (Wallington *et al.*, 1997).

The availability of transparent coatings with a wide variety of matrices, along with the possibility to entrap biomolecular dopants, opened the door to the development of biosensors from Sol-gel coatings (Jerónimo *et al.*, 2007). The immobilized biomolecules maintain their biological functions and structures inside the Sol-gel matrix. Blyth *et al.* (1995) developed the first biosensor by Sol-gel for nitrogen monoxide and carbon monoxide detection, revealing that thin films are more efficient for bio-detection than monoliths. Enzymes like oxidoreductases and glucose oxidases remains active within the Sol-gel matrix and different sensing systems are still being developed (Ramanathan *et al.*, 1997).

Biomaterials Made by Sol-Gel

Sol-gel materials have been extensively studied for biomedicine and biomedical applications, including the design of materials in bio-sensing and bio-production (Avnir *et al.*, 2006). Nowadays, Sol-gel biomaterials are used in bio-encapsulation and drug release applications and as innovative bioactive materials. The behavior of a specific biomolecule in the inorganic, organic or hybrid nanocomposite material environment, determines the possibilities of these biomolecules to keep their native properties (Jin and Brennan, 2002).

Enzyme-based biosensors are an important field under development. Fukushima *et al.* (1988) and Jin and Brennan (2002) reported the immobilization of cells and enzymes using Sol-gel, demonstrating the good efficiency. Different compositions and hybrid organic-inorganic sol gel materials are reported for reducing the denaturalization of the enzymes during the aging of the inorganic network (Ellerby *et al.*, 1992; Gill and Ballesteros, 2000; Livage *et al.*, 2001).

Tan *et al.* (2005) stated for the first time a hybrid composite made with chitosan/silica, one of the most studied composites nowadays (Zhou *et al.*, 2015; Spirk *et al.*, 2013; Budnyak *et al.*, 2014). Hybrid chitosan and silica are suitable for cholesterol oxidase, amylase, urease, catalase and invertase. Similar hybrid systems are used for cell encapsulations. Sol-gel is a rapid process for immobilizing cells into a stable biomatrix; (Alvarez *et al.*, 2007) demonstrated the high activity and longevity of cells entrapped in silica matrix.

On the other hand, porous Sol-gel materials with cationic amino groups that interact with alginate are demonstrated to be suitable for proliferation and insulin secretion both in vivo and in vitro. Sakai *et al.* (2001) designed a Sol-gel synthesis route for preparing microcapsules with double layer of alginate used in bio-artificial pancreas. These organic-inorganic microcapsules derived from Sol-gel are thus suitable for use in the field of bio-artificial organs.

Sol-gel process is also applied in the biomedical field as implants and sensors where a molecular control of hydroxyapatite incorporation is required, together with the biological behavior of proteins and cells (Hench, 1997). These materials do not provoke rejection by the human body and over time, they are partially reabsorbed and replaced by natural bone.

Bioactive Sol-gel materials shaped as coatings, monoliths or powders are used to obtain an efficient bond to bone by chemical reactions occurring at the interface of the bone tissue that improve the nucleation of the hydroxyapatite. These bioactive Sol-gel materials promote hydroxyapatite multilayer formation on the bone tissue, both in vivo and in vitro. Pereira and Hench (1996) described the mechanism of hydroxyapatite formation on different gel silica substrates. Sepulveda *et al.* (2001) made a full comparison between bioactive glasses made by melt quenching and by Sol-gel, obtaining remarkable differences in the surface area. The biocompatibility of the implant is determined not only by the availability of growth of the apatite, but also by the capacity to absorb proteins (Lobel and Hench, 1996).

There is a clinical need for materials to stimulate the repair of bone by kindling the body's own healing mechanisms. Bone can heal itself if the defect is small, but needs assistance if the defect is over a critical size. Temporary templates (scaffolds) act as guides and stimulus for vascularised bone growth. Inherently brittle materials cannot be used in applications that experience cyclic loads, the current bioactive materials needing toughness and plasticity. The obvious way to improve toughness is to make a composite material, using a bioactive ceramic or glass as the inorganic phase within a biodegradable polymer as the organic matrix. The degradation can be made more congruent by careful polymer selection and manipulation or by developing specialized types of nanocomposites. Jones and Valliant (2011) and Martin *et al.* (2012) tried to understand how each property of the glass and hybrid

Fig. 8 X-ray microtomography images of (a) bioactive glass foam scaffold and (b) trabecular bone. Reproduced from Martin, R.A., Yue, S., Hanna, J.V., *et al.*, 2012. Characterizing the hierarchical structures of bioactive sol-gel silicate glass and hybridscaffolds for bone regeneration. *Philosophical Transactions of the Royal Society A* 370 (1663), 1422–1443.

scaffolds affects cellular response to optimize the materials and ensure long-term success and clinical products. They focused on the characterization of the hierarchical structures of Sol-gel glasses and hybrids, from atomic-scale amorphous networks, through the covalent bonding between components in hybrids and nanoporosity, to quantifying open macroporous networks of the scaffolds. Nondestructive in situ monitoring of degradation and bioactivity mechanisms of the materials are also included (Fig. 8).

Boccaccini and Zheng (2017) reviewed silicate-based bioactive glass nanoparticles (BGN) with unique properties in biomedical applications. Sol-gel synthesis of BGN is drawing widespread attention, because the convenience and versatility it offers to tune the properties of BGN. Considering the importance of the BGN morphology and composition to their biomedical applications, strategies to control the size, shape, pore structure and composition of BGN are relevant. BGN are particularly interesting biomaterials for bone related applications, but they also have potential for other biomedical applications, e.g., in soft tissue regeneration/repair.

Other Applications

Sol-gel process permits (Boccaccini and Zheng, 2017) preparation of a wide range of outstanding products; some of them gave rise to special fields of research inside the Sol-gel community.

Aerogels have unique properties due to the possibility of controlling the shape and size of pores at low processing temperatures. The extremely low density of these materials explains their amazing thermal and acoustic insulation properties. Aerogels are used as composites (Shajesh *et al.*, 2009; Moner-Girona *et al.*, 2002), absorbents (Rao *et al.*, 2007) and sensors, and have a huge variety of possible science and technology applications (Gurav *et al.*, 2010).

Brinker and Scherer (1985) reported the fabrication of fibers as a new field of applications of Sol-gel materials. Fibers prepared by Sol-gel can be used for reinforcement, superconducting, electrolytic or optical applications, as well as for improving chemical durability (Russel-Flores *et al.*, 1993; Sakka, 1990).

Different Sol-gel routes continue to be active for preparing Fe_2O_3 -C fibers for anodes in Li-ion batteries (Changbin *et al.*, 2018) and PES-TiO₂ hollow fiber hybrid membranes were recently reported by Lu *et al.* (2017). Sol-gel xerogels are applied as sensors and fuel cells taking advantage of the elevated controlled porosity (Grattan *et al.*, 1991; Li *et al.*, 2011).

In the field of optical applications, bulk gels and monoliths are essential parts of fiber optics, lenses, glasses with graded refractive index, etc. (Grant and Glass, 1997).

Introduction

Although glass crystallization has been known for a long time, the use of this phenomenon in a systematic, controlled way for the development of glass-ceramics for industrial applications only began in the 1960s. The glass-ceramics developed over the last 60 years have various useful properties: thermal resistance, transparency, mechanical resistance, bioactivity. The objectives of this chapter are first to give general information about the glass-ceramic process and its advantages over the conventional ceramic process, and then to present applications of some glass-ceramics systems according to their main properties. Note that a given glass-ceramic system often combines multiple attributes, making it useful for various applications. Examples of compositions or trademarks are given where they are significant in their field of application, but it should be noted that many other glass-ceramics exist or are under development.

Glass-ceramics are polycrystalline materials resulting from the controlled crystallization of a glass precursor, also called parent glass. As shown in Fig. 1, the first step of the process is the melting and the shaping of the glass. This step can be achieved by conventional glassmaking techniques such as rolling, pressing or casting, but also by using alternative routes such as sol-gel, CVD (Chemical Vapor Deposition). One or several crystalline phases are subsequently obtained by controlled nucleation and crystallization during the crystallization heat-treatment. Fig. 2 shows the microstructure of the final material which is usually predominantly crystalline, although it may contain a significant volume fraction of residual glass.

The properties of the final glass-ceramic are mainly governed by the properties of the crystalline phases, their volume fractions and their microstructures. However, the amount of residual glass and its properties also play an important role, for example through its influence on the interconnectivity of the crystalline phase. Taking this into account, numerous glass-ceramics exhibit very good mechanical/thermomechanical properties in combination with functional properties (electrical, optical, biological ...).

Among the numerous advantages of the glass-ceramic process over the ceramic powder route, the following can be highlighted:

- (1) Glass-ceramics are generally highly homogeneous and pore free;
- (2) Crystallites can exhibit various morphologies and sizes, allowing for instance nanostructured materials;
- (3) According to the crystallization mechanism, the crystals can be randomly or preferentially orientated in the glass-ceramic and respectively lead to isotropic or anisotropic properties;
- (4) Metastable phases can be produced;
- (5) Glassmaking techniques allow various shapes and large size parts;
- (6) Large size transparent or translucent parts can be produced;
- (7) Tight geometric and dimensional tolerances can be achieved as crystallization usually leads to very low volume variations.

The overwhelming majority of glass-ceramics are made up of oxide compounds produced from silicate parent glasses although phosphate or mixed silicate/phosphate glass-ceramics are also encountered, for example in electrical and biomedical applications. Some systems such as $\text{Li}_2\text{O}-\text{Al}_2\text{O}_3-\text{SiO}_2$ (LAS) with β -eucryptite (LiAlSiO_4) or β -spodumene ($\text{LiAlSi}_2\text{O}_6$) crystals and $\text{MgO}-\text{Al}_2\text{O}_3-\text{SiO}_2$ (MAS) with cordierite ($\text{Al}_4\text{Mg}_2\text{Si}_5\text{O}_{18}$) crystals are widely used, mainly for their superior thermomechanical properties.

Microstructure and Synthesis

Most of the applications of the glass-ceramics require homogeneous and isotropic microstructures. Growth of crystals is schematized in Fig. 3(a), and must take place on nuclei well dispersed in the whole volume of the parent glass. In some rarer cases, the targeted properties can only be obtained through a highly preferential orientation of the crystals. This can be achieved by promoting a surface nucleation, and subsequently the propagation of a crystallization front from the surface into the bulk as shown in Fig. 3(b).

Although occurring for some glass compositions, resulting in formation of $\text{Li}_2\text{Si}_2\text{O}_5$, BaSi_2O_5 or $\text{Si}_2\text{P}_2\text{O}_7$ crystals, spontaneous bulk (volume) homogeneous nucleation is rare and surface nucleation at lower energy sites is the rule. However, heterogeneous bulk nucleation can be induced by adding nucleation agents, either oxides such as TiO_2 (rutile or anatase), ZrO_2 , ZrTiO_4 and Cr_2O_3 or noble metals such as Au or Ag, in the parent glass composition. These compounds produce a phase separation in the parent glass that initiates the nucleation.

Theory of nucleation and crystallization in glass-ceramics has been widely investigated (James, 1989; Müller *et al.*, 2000). However, application of models to practical cases is rather complex. Basically, the nucleation rate I is a function of the temperature T that goes through a maximum at temperature T_n usually around a hundred degrees above the glass transition temperature T_g of the parent glass. Once nuclei are formed in the glass, crystallization results from the epitaxial growth of the crystalline phase. Growth rate J is related to the transfer equilibrium of new atoms at the surface of the crystal. Growth rate also goes through a

Fig. 1 Process flowsheet usually followed to manufacture glass-ceramics.

Fig. 3 Schematic representation of nucleation and crystal growth. Volume (a) and surface (b) mechanisms.

maximum at a temperature T_c higher than T_n . **Fig. 4** exhibits the nucleation and growth rates over temperature. The temperature dependent characteristics of the parent glass that strongly influence the nucleation and growth rates of the crystals are the viscosity η and the surface tension σ . A lower viscosity η increases the atomic diffusion from the parent glass to the crystals, while the reaction rate between the atoms and the crystal surface is governed by the surface tension σ .

Fig. 4 Schematic illustration of the variation of nucleation rate and growth rate with temperature.

Fig. 5 Schematic illustration of the temperature profile of a 2-stage crystallization heat-treatment.

Key Points of the Process

The crystalline phases formed during the crystallization treatment, their volume fractions, and their microstructure are dependent on the parent glass composition and the heat treatment conditions. Consequently, the requirements to process a glass-ceramic are that the elements of the targeted crystalline phases must be compatible with a low enough melting temperature of the glass and that it does not crystallize in the temperature range required for the shaping step. Subsequently, if the difference between T_n and T_c is high enough, a control of the microstructure through nucleation and growth is possible by a two-stage heat treatment as illustrated in [Fig. 5](#).

In most cases, the density of the crystals formed is higher than that of the parent glass. Conversely, the density of the residual glass is usually lower. As a result, the difference in density between the parent glass and the final glass-ceramic, and consequently the dimensional variations during crystallization, are weak. It should be noted that as crystallization is operated at a temperature significantly higher than T_g , the internal stresses that may result from these volume changes are rapidly relaxed. However, a low viscosity as a result of a high temperature can lead to geometric distortion. Consequently, the viscosity of the parent glass at the crystallization temperature must be kept between 10^9 and 10^{11} Pa s to allow stress relaxation but prevent sagging. Distortions can also result from temperature gradients leading to a non-homogeneous crystallization. As crystallization is an exothermal reaction, this problem is exacerbated for large size parts of low thermal conductivity. It is also important to emphasize that, due to the difference of thermal expansion between the different phases composing the glass-ceramic, internal stresses are created when cooling below T_g (i.e., in the elastic domain) after the crystallization treatment. Even if in some cases these stresses may lead to the reinforcement of the material, they may also affect the performance, as for example the thermal fatigue resistance.

For some applications requiring specific geometries, such as dielectric multilayer substrates for instance, shaping cannot be realized by glassmaking techniques at the initial stage of the parent glass. This is also the case for glass compositions showing a risk of uncontrolled crystallization during cooling. In those cases, the ceramic powder process, from a parent glass powder (i.e., pressing, casting..., and subsequent sintering), is used. Note that by this processing route, the glass powder is sometimes mixed with ceramic powders to form a “composite” material.

Fig. 6 Mechanism of chemical strengthening by ion exchange in RbNO_3 salt. Reproduced from Shan, Z., Liu, J., Liu, M., *et al.*, 2018. Surface strengthening of lithium disilicate glass-ceramic by ion-exchange using Rb, Cs nitrates. *Ceramics International* 44, 12466–12471.

Applications of Glass-Ceramics Exploiting Thermomechanical Properties

The good thermomechanical properties and the low cost of glass-ceramics make them very useful for a large range of applications. Missile nose cones, called radomes, were the very first application of glass-ceramics, before kitchenware (Suzdal'tsev *et al.*, 2010). Pyroceram® (Corning) was used for its thermal shock resistance and erosion resistance, years before it arrived on kitchen shelves. In the context of the Cold War, the USSR developed some glass-ceramics such as AS-418 and AS-370. Note that glass-ceramics are sometimes referred to as "sitalls" in papers from former Soviet Union countries.

Thermal-Shock Resistance

Some glass-ceramics systems are characterized by low thermal expansion coefficients that, associated with a rather good mechanical strength, provide a high resistance to thermal shock. This property combined with good transparency, is the origin of the commercial success of glass-ceramics in the field of inexpensive kitchen utensils and cookware (Bach and Krause, 2005). The first commercial product was called Pyroceram® 9608 (Corning), with a thermal expansion of $0.7 \times 10^{-6} \text{K}^{-1}$, and that mainly contained β -spodumene solid solutions ($\text{LiAlSi}_2\text{O}_6 - \text{SiO}_2$) with rutile (TiO_2) as minor phase (added as nucleating agent). Since then, other materials containing β -spodumene have been developed such as Cer-Vit™ (Owens-Illinois), Hercuvit™ (PPG), or Neoceram™ N-11 (Nippon Electric Glass). All these materials are white. Glass-ceramics containing β -quartz solid solutions are suitable for transparent products. Several compositions of this type of glass-ceramic have been developed, such as Vision® (Corning), Ceran® (Schott), Neoceram™ N-0 (Nippon Electric Glass), or Kerablack® (Eurokera). These materials are still used in everyday life, especially in cooktops.

High Mechanical Properties

High strength and high toughness glass-ceramics are obtained by crystallization of a glass that leads to particular microstructures made of interlocking crystals. This is the case with crystallization of enstatite (MgSiO_3), potassium fluorrichterite ($\text{KNaCaMg}_5\text{Si}_8\text{O}_{22}\text{F}_2$), and fluorcanasite ($\text{K}_2\text{Na}_4\text{Ca}_5\text{Si}_{12}\text{O}_{30}\text{F}_4$) that leads to high flexural strength ($> 200 \text{ MPa}$) and high fracture toughness ($> 3 \text{ MPa m}^{1/2}$) (Beall, 1991; Mirsaneeh *et al.*, 2006). Lithium disilicate and miserite glass-ceramics are also very strong (Pinckney *et al.*, 1999). All of these glass-ceramics are extensively used for medical applications.

High strength glass-ceramics were also developed by using the ion exchange technique (Beall *et al.*, 2016). This method consists in the exchange of alkali ions (of the residual glass or crystal phase) by larger ones by soaking the material in a bath of molten salt. As shown in Fig. 6, it results in a compressive stress layer at the surface and a stress profile over depth, which increases the strength. The $\text{SiO}_2\text{-Al}_2\text{O}_3\text{-MgO}$ system in Li_2SO_4 bath (Mg^{2+} exchanged by 2Li^+) was experimented first and led to an increase of the fracture strength of around 300 MPa (Beall *et al.*, 1967). The $\text{SiO}_2\text{-Al}_2\text{O}_3\text{-Li}_2\text{O}$ system is also used by exchanging Li^+ ions for

Fig. 7 Beam-bending viscosity vs. temperature of a Sr-feldspar glass-ceramic. Reproduced from Beall, G.H., 2009. Refractory glass-ceramics based on alkaline earth aluminosilicates. *Journal of the European Ceramic Society* 29, 1211–1219.

Na^+ or K^+ (Takeuchi *et al.*, 1997). This strengthening process is still under investigation for more complex systems (Beall *et al.*, 2016; Fischer *et al.*, 2008; Ponsot *et al.*, 2014).

Some high strength and high toughness glass-ceramics are developed for armor applications such as bulletproof vests and vehicle protection. Transparent materials such as Transarm® (Alstom) and Resistan® (Schott) are also developed for armored windows. Due to the military use of these material, compositions are usually not disclosed, but many systems are used such as $\text{Li}_2\text{O}-\text{SiO}_2$, $\text{Li}_2\text{O}-\text{Al}_2\text{O}_3-\text{SiO}_2$, $\text{MgO}-\text{Al}_2\text{O}_3-\text{SiO}_2$, $\text{Li}_2\text{O}-\text{ZnO}-\text{SiO}_2$ and more (Benítez *et al.*, 2017).

The crystallization of a layer at the surface of a glass is investigated as an alternative to heat or chemical strengthening of a glass. The surface then shows a lower expansion coefficient than the glass, so the surface layer is under compressive stress after cooling. Glass-ceramics from the $\text{SiO}_2-\text{Al}_2\text{O}_3-\text{Li}_2\text{O}$ system were successfully surface reinforced by surface crystallizing β -eucryptite and β -spodumene (Priller *et al.*, 1996). The $\text{SiO}_2-\text{Al}_2\text{O}_3-\text{ZnO}$ system is also of interest (Bocker *et al.*, 2017). Other more complex systems are under investigation (Teixeira *et al.*, 2019).

Very High Temperature Use

Applications of glass-ceramics are usually limited to temperatures below 1000°C due to the decrease of their mechanical properties as a result of the decrease of the residual glass viscosity, or because of thermal decomposition, or both. This deterioration is unavoidable, but a glass-ceramic containing strontium and barium feldspar crystals of the celsian type showed no deformation up to 1450°C as shown in Fig. 7 (Beall, 2009). Its linear thermal expansion is about $4 \times 10^{-6}\text{K}^{-1}$ and its parent glass melts at 1650°C . Mullite glass-ceramics containing a high level of excess silica can be used at 1550°C without deformation but the parent glass melting point reaches 1750°C .

Specific Uses

Glass-ceramics with a near zero coefficient of thermal expansion are used for very specific applications. Zerodur® (Corning) is extensively used in telescope mirrors thanks to its very high homogeneity regarding its thermal expansion and its very low level of bubbles (Döhning *et al.*, 2008; Jedamzik *et al.*, 2006). It was characterized for use as mirror blanks in extremely large telescopes with diameter superior to 30 m (Döhning *et al.*, 2006). Fig. 8 shows the Zerodur mirror developed for the Extremely Large Telescope. Astrosital® (LZOS - Lytkarino Optical Glass Plant) is also used for telescope mirrors. Glass-ceramics with specific thermal expansion are used in reflectors and gyroscopes (Covino and Bennett, 1986).

Glass-Ceramics for Bonding and Sealing

Glass-Ceramic-to-Metal Bonding

Glass-to-metal bonds are extensively used in many applications such as lamp bulb seals, but it has limits. Glass-ceramics are more suitable for this purpose because of their higher mechanical properties, better temperature resistance, and tunable thermal

Fig. 8 Secondary mirror for the extremely large telescope made of Zerodur® (Credit to Schott).

Fig. 9 Cross-section view of glass-ceramic coated Ti6Al4V alloy. Reproduced from Sanyal, S., Shukla, M., Dandapat, N., Ghosh, S., 2018. In vitro evaluation of bioactive glass ceramic coating for application on Ti6Al4V based biomedical implants. *Journal of Non-Crystalline Solids* 500, 22–29.

expansion. To realize such seals, the glass is applied as a slurry and crystallized in an environment that prevents the metal from oxidizing. The glass-ceramics can be used as coatings or as seals between multiple metallic parts.

Fe-based alloys have a wide range of thermal expansion coefficients from 3 to $18 \times 10^{-6} \text{K}^{-1}$ depending on their composition. For mild steel, pre-oxidation leads to the formation of non-stoichiometric FeO that induces a diffusion of Fe^{2+} . This diffusion creates a thermal expansion gradient at the interface which would be beneficial if it were not accompanied by a stress gradient. Atmosphere and processing must therefore be well controlled to form Fe_2O_3 rather than FeO. Glass-ceramics from the $\text{Li}_2\text{O}-\text{ZnO}-\text{SiO}_2$ (LZS) and $\text{Li}_2\text{O}-\text{Al}_2\text{O}_3-\text{SiO}_2$ (LAS) are effective sealants for many Fe-based alloys. Precipitated phases such as iron phosphide and chromium silicide tend to form at the interface, but the addition of CuO in the glass suppresses this problem and a clean oxide interface can be formed (Donald *et al.*, 2011).

Titanium and Ti-based alloys are mainly used in the aerospace industry or in orthopedic implants. The thermal expansion coefficient of the most widely used alloy for industrial application Ti6Al4V is $9.4 \times 10^{-6} \text{K}^{-1}$, and pure Ti thermal expansion is $9.2 \times 10^{-6} \text{K}^{-1}$ (Staff *et al.*, 2016). Lithium silicate glass-ceramics are often used to coat Ti dental implants because it is therefore possible to obtain tunable esthetic properties, similar to those of a tooth. They are also used on ceramic dental restorations. For Ti6Al4V alloys, glass-ceramic coatings from the $\text{SiO}_2-\text{CaO}-\text{Na}_2\text{O}-\text{MgO}-\text{P}_2\text{O}_5-\text{K}_2\text{O}$ and $\text{SiO}_2-\text{Al}_2\text{O}_3-\text{CaO}-\text{P}_2\text{O}_5-\text{CaF}_2$ systems were successfully used (Verné *et al.*, 2004; Sanyal *et al.*, 2018). Fig. 9 shows an example of glass-ceramic coating on Ti6Al4V.

Ni-based superalloys are mostly used in high temperature parts of turbine engines because of their good thermomechanical properties and high corrosion resistance. Depending on their composition, they exhibit thermal expansion coefficients from 12 to

Fig. 10 Example of sealing configuration in planar SOFCs. Reproduced from Tulyaganov, D.U., Reddy, A.A., Kharton, V.V., Ferreira, J.M.F., 2013. Aluminosilicate-based sealants for SOFCs and other electrochemical applications – A brief review. *Journal of Power Sources* 242, 486–502.

$16 \times 10^{-6} \text{K}^{-1}$ (Donald *et al.*, 2011). Lithium silicate glass-ceramic with an addition of 2% ZnO was used to seal Inconel 600, Haynes 230, and Hastelloy C-276. However, the interfaces degrade at 800°C , except for Inconel 600 which deteriorates between 800°C and 900°C (Bengisu *et al.*, 2004). Glass-ceramics from the $\text{ZnO-Al}_2\text{O}_3\text{-SiO}_2$ system can operate up to 1000°C but may be porous, so a mix with BaO-MgO-SiO_2 glass is required to create a fully protective coating (Datta and Das, 2005). BaO-MgO-SiO_2 based glass-ceramics were also used alone as a bonding layer between a Nimonic alloy AE 435 substrate and a 8 wt% Ytria Stabilized Zirconia top coat (Ghosh, 2014).

Sealants in Solid Oxide Fuel Cells

Solid oxide fuel cells (SOFC) are devices producing electricity directly from the oxidation of a fuel. A solid electrolyte (e.g., yttrium-doped zirconia YSZ) is used to carry the oxygen ions from the cathode to the anode. SOFC operate at high temperatures, i.e., from 650 to 1000°C , to allow the electrolyte to reach a sufficiently high ionic conductivity. One advantage of a high working temperature is that expensive catalysts are avoided and consequently the device is not vulnerable to carbon monoxide catalyst poisoning. However, SOFC batteries are composed of multiple interconnected cells joined by hermetic gas sealants that must withstand the working temperatures for long times. Fig. 10 shows the schematic of a planar SOFC.

The material used as SOFC seals must show the following features: chemical stability in oxidizing and reducing atmospheres, chemical compatibility, electrical insulation, high bond strength, hermeticity, long service life when exposed to high temperature and thermal cycles, and a coefficient of thermal expansion from 10 to $12 \times 10^{-6} \text{K}^{-1}$. Glass-ceramics are the most commonly used materials as sealants for SOFC batteries. These glass-ceramics belong to different systems, but their service life in the aggressive environment of the battery remains a problem for long-term operation.

Phosphate glass-ceramics showed volatilization and reaction with the nickel-zirconia cermet anode at operating temperature, along with a decomposition in a humidified fuel atmosphere (Lessing, 2007). Many barium aluminosilicate glass-ceramics react with the interconnect leading to delamination (Tulyaganov *et al.*, 2013). A high boron content forms volatile compounds with water vapor, degrading the seal. However, many of the developed glass-ceramics are boro-silicate based because boron decreases the viscosity, but the boron content is often lowered to reduce the degradation problems. Different boro-silicate based systems were explored over the years such as $\text{MgO-BaO-B}_2\text{O}_3\text{-SiO}_2$ (Rodríguez-López *et al.*, 2016), $\text{MgO-BaO-B}_2\text{O}_3\text{-SiO}_2\text{-TiO}_2$, $\text{MgO-B}_2\text{O}_3\text{-Al}_2\text{O}_3\text{-SiO}_2$, $\text{BaO-B}_2\text{O}_3\text{-Al}_2\text{O}_3\text{-SiO}_2$, $\text{SrO-La}_2\text{O}_3\text{-B}_2\text{O}_3\text{-Al}_2\text{O}_3\text{-SiO}_2$, $\text{BaO-MgO-SrO-Al}_2\text{O}_3\text{-B}_2\text{O}_3\text{-SiO}_2$, or $\text{BaO-MgO-Al}_2\text{O}_3\text{-B}_2\text{O}_3\text{-SiO}_2$ (Lessing, 2007; Ley *et al.*, 1996). Boron-free glass-ceramics were also developed to prevent degradation and therefore create more durable sealants. These later belong to different systems such as $\text{CaO-Na}_2\text{O-Al}_2\text{O}_3\text{-SiO}_2$ with addition of MgO , La_2O_3 or ZnO (Smeacetto *et al.*, 2010), $\text{Na}_2\text{O-SiO}_2$ with addition of Fe_2O_3 (Lin *et al.*, 2018b), $\text{SrO-La}_2\text{O}_3\text{-Al}_2\text{O}_3\text{-SiO}_2$ (Jin and Lu, 2010), or $(\text{CaO,MgO,ZnO})\text{-Al}_2\text{O}_3\text{-BaO-SiO}_2$ (Lara *et al.*, 2004). Researches on other battery compounds aim at reducing the operating temperature of SOFCs, which would allow the use of glass-ceramics without any degradation.

Joining for SiC-Based Materials

SiC and SiC-based materials are considered for different high temperature applications, especially in jet engines, reentry vehicles, and fusion and fission reactors thanks to its irradiation stability, chemical inertness, toughness, and high temperature performance. However, complex or large SiC-based parts cannot be manufactured easily, so joining them is mandatory for a larger scale use. Joining of SiC composite parts is difficult because the joint needs to be resistant to fluxes of high energy neutrons and to high

Fig. 11 Micrograph of the cross-section of a SiC/SiC joined SAY glass-ceramic. Reproduced from Ferraris, M., Salvo, M., Casalegno, V., *et al.*, 2008. Joining of machined SiC/SiC composites for thermonuclear fusion reactors. *Journal of Nuclear Materials* 375, 410–415.

temperature gradients. It is possible to produce glass-ceramics with the required properties, and their pressureless joining process makes them advantageous. **Fig. 11** shows an example of glass-ceramic joint between two SiC/SiC composites.

The most explored systems are $\text{CaO-Al}_2\text{O}_3$ (CA) and $\text{Y}_2\text{O}_3\text{-Al}_2\text{O}_3\text{-SiO}_2$ (SAY). CA glass-ceramics show a high temperature stability with a softening point around 1300°C . SiC/SiC joined with CA were mechanically tested, and a shear strength of 104 ± 25 MPa was measured through torsion tests (Salvo *et al.*, 2013). The microstructure and damaging of CA glass-ceramics were observed after Si-ion irradiation (Casalegno *et al.*, 2018). SiC/SiC joined with a SAY glass-ceramic exhibits a bending strength of 120 MPa at room temperature. Irradiation tests were carried out, and the joint was maintained after irradiations of 16.3×10^{24} n m^{-2} at 600°C and $31\text{--}32 \times 10^{24}$ n m^{-2} at 820°C . Bending tests before and after irradiation proved that the mechanical properties of the joint were not affected (Ferraris *et al.*, 2012). Glass-ceramics containing rare-earth aluminosilicates were also developed using $\text{RE}_2\text{O}_3\text{-Al}_2\text{O}_3\text{-SiO}_2$ (RE: Nd, Dy, Ho, Y, Yb, or Sc) systems. These were used to join two SiC rods through laser-assisted heating, and 4-point bending strength and He leak-rate tests were realized at room temperature after thermal treatments. Glass-ceramic containing Nd exhibited a high bending strength of 149 MPa, followed by Ho (136 MPa), Y (132 MPa), and Dy (126 MPa). Helium leak rates of about 10^{-10} mbar L s^{-1} are obtained for different thermal treatments depending on the composition, so the joints are gas tight ($< 10^{-8}$) (Herrmann *et al.*, 2017).

Some materials are very promising for SiC and SiC-based materials joining to form complex assemblies, but there is a lack of complete high temperature characterization regarding the mechanical properties, leak rates, and irradiation resistance.

Application of Glass-Ceramics in the Field of Healthcare

Most of the glass-ceramics are biocompatible materials able to be implanted in a living body without poisoning it or being rejected. Some even show bioactive or bioresorbable properties. This means that they integrate a biological process, for instance by forming a biologically active layer on its surface that allows creating bonds with the tissues (El-Meliagy and Van Noort, 2011). These properties allow glass-ceramics to be used for implants.

Bioactive Glass-Ceramics for Implant and Bone Tissue Regeneration

Usual bioactive materials are ceramics (e.g., hydroxyapatite) and glasses (e.g., 45S5 Bioglass®). However, bioceramics are quite complex and expensive to produce and bioactive glasses exhibit low mechanical strength and toughness. Dense bioactive glass-ceramics are easy to synthesize through glassmaking techniques and their mechanical properties are higher than those of glasses. The bioactive glass-ceramics used, or under development, are mainly composed of SiO_2 , P_2O_5 , CaO and MgO with addition of CaF_2 , Na_2O or K_2O (Vitale-Brovarone *et al.*, 2008; Mahato *et al.*, 2017; Kokubo, 1991).

Porous glass-ceramics with complex shapes can also be obtained by powder sintering of a porous green body shaped by techniques such as polymer foam replication, solution combustion, freeze casting or 3D printing (Gerhardt and Boccaccini, 2010). **Fig. 12** shows the porous structure of a glass-ceramic derived from 45S5 Bioglass®.

Some glass-ceramics are currently used for clinical applications. Ceravital® (Ernst Leitz, Wetzlar) was developed in 1973 and was the first glass-ceramic for clinical use. It contains apatite and its composition evolved over time, but its low mechanical properties make it useful only for low load-bearing parts, such as replacement of the ossicular chain in the middle ear. Cerabone® (Nippon Electric Glass) is made of apatite-wollastonite with a very fine microstructure that induces high mechanical

Fig. 12 Pore structure and microstructure of 45S5 Bioglass®-derived foams sintered at (a)–(b) 900°C for 5 h; (c)–(d) 950°C for 2 h; and (e)–(f) 1000°C for 1 h. Reproduced from Chen, Q.Z., Thompson, I.D., Boccaccini, A.R., 2006. 45S5 Bioglass®-derived glass-ceramic scaffolds for bone tissue engineering. *Biomaterials* 27, 2414–2425.

properties and strong bond with bones, leading to its use in reconstructing iliac crests, vertebrae, intervertebral disks, and as filling powder for bone defects (De Aza *et al.*, 2007). Ilmaplant-L1® is an apatite-wollastonite glass-ceramic exclusively used for maxillofacial implants. Bioverit I® and Bioverit II® are glass-ceramics containing apatite and fluorophlogopite mica which are used in orthopedic surgery (e.g., ligament fixation of the knee, tibial plateau, replacement of vertebrae and osteotomy) or head and neck surgery (e.g., rhinoplasty, maintenance of orbit, and reconstruction of skull base, auditory canal, and frontal sinus) (Höland and Vogel, 2013).

Research on the synthesis of new bioactive glass-ceramics coupled with the development of new forming techniques is still abundant to this day. The objectives are to improve the bioactivity, mechanical properties, and formability of glass-ceramics in order to use them for the rapid regeneration of any bone in the human body.

Hyperthermia Treatments of Cancerous Tumors

The amount of blood vessels in tumors is lower than in healthy tissues, so a high temperature (around 43°C) can destroy cancer cells without harming the surrounding tissues, or at least make them more sensitive to other treatments such as chemotherapy or radiotherapy (Abdel-Hameed *et al.*, 2009). Glass-ceramics containing ferrimagnetic particles (usually magnetite Fe_3O_4), which can be heated by induction, are of potential interest for the development of these hyperthermia treatments. Numerous types and compositions of glass-ceramics have been investigated and applied with reference to the treatment of different types of cancer cells. In addition, some of these glass-ceramics are bioactive. In the case of tumorous bone tissue, they can bond to the tissues and increase the recovery after destroying the tumor. As listed in recent reviews (Miola *et al.*, 2018; Lin *et al.*, 2018a), many systems

Fig. 13 Lithium disilicate molar crown milled by CAD/CAM technique. Reproduced from Sadid-Zadeh, R., Kastavochristou, A., Squires, T., Simon, M., 2019. Accuracy of marginal fit and axial wall contour for lithium disilicate crowns fabricated using three digital workflows. *Journal of Prosthetic Dentistry* 123, 121–127.

were explored to improve the magnetic and bioactive properties, such as $\text{Fe}_2\text{O}_3\text{--CaO--SiO}_2\text{--B}_2\text{O}_3\text{--P}_2\text{O}_5$ (Kokubo, 1991), $\text{SiO}_2\text{--Na}_2\text{O--CaO--P}_2\text{O}_5\text{--FeO--Fe}_2\text{O}_3$ (Bretcanu *et al.*, 2006), and $\text{CaO--SiO}_2\text{--P}_2\text{O}_5\text{--Na}_2\text{O--Fe}_2\text{O}_3$ (Singh *et al.*, 2008). In vivo studies remain to be conducted to confirm the potential of use of these materials.

Dental Restoration

Materials used for dental restoration are not implanted, but are bonded to existing teeth. They require high mechanical properties to be as resistant as a natural tooth, good durability in the oral environment and esthetic properties (Denry and Holloway, 2010). Multiple glass-ceramic compositions were synthesized and are now commonly used for inlays, onlays, crowns, and bridges. Glass-ceramic veneers also exist to modify the aspect of the restoration in order to obtain the same color (hue, chroma and value), fluorescence, opalescence, and opacity as the patient's teeth. Veneers can be applied on glass-ceramic or metallic restoration parts (Pini *et al.*, 2012).

The major crystalline phases of the mostly used glass-ceramics for dental restoration are fluoromica (e.g., DICOR®, Corning/Dentsply), leucite (e.g., IPS Empress®, Ivoclar Vivadent), leucite-apatite (e.g., IPS d. SIGN®, Ivoclar Vivadent), lithium disilicate (e.g., IPS e.max® CAD, Ivoclar Vivadent), and sanidine (Vitablocks® Mark II, Vita Zahnfabrik) (Shenoy and Shenoy, 2010; Pröbster *et al.*, 1997; Montazerian and Zanotto, 2017). Specific fluorapatite glass-ceramic veneers exist for lithium disilicate restoration such as IPS e.max® Ceram. Glass-ceramics crystallized from the $\text{Li}_2\text{O--P}_2\text{O}_5\text{--ZrO}_2\text{--SiO}_2$ are used to cover ZrO_2 root posts before applying a glass-ceramic crown (e.g., IPS Empress Cosmo®, Ivoclar Vivadent) (Montazerian and Zanotto, 2017).

Even though glass-ceramics are very useful for dental restoration, only lithium disilicate has a high enough fracture resistance to be used in posterior teeth restoration as in Fig. 13. Other crystalline phases are also under investigation, such as fluorrichterite $\text{KNaCaMg}_5\text{Si}_8\text{O}_{22}\text{F}_2$, fluorcanasite $\text{K}_2\text{Na}_4\text{Ca}_5\text{Si}_{12}\text{O}_{30}\text{F}_4$, and apatite-mullite $\text{Ca}_{10}(\text{PO}_4)_6\text{F}_2\text{--}3\text{Al}_2\text{O}_3\text{--}2\text{SiO}_2$ (Pollington, 2011). Diopside glass-ceramics are also investigated for ZrO_2 veneering.

Electrical Applications of Glass-Ceramics

Insulators

Withstanding high voltages is an essential requirement for insulators in the field of electrical engineering and solid-state electronics. In addition, a good thermal conductivity, a low thermal expansion, and a thermal stability of the electrical properties is required as significant heating can be produced in high performance electric devices. Dielectric breakdown is related to defects acting as sources of local electrical stress concentration. In conventional ceramic dielectrics, porosity, crystallographic defects, impurities, grain boundaries or interfaces with secondary phases seriously affect their performances. Low porosity and low grain size improve the breakdown resistance. On that point, the advantage of glasses is their high homogeneity and the absence of pores. Thus, their electrical breakdown strength can be an order of magnitude higher than that of the conventional ceramic dielectrics. However, most of the glasses exhibit high dielectric losses. In this regard, glass ceramics from the $\text{MgO--Al}_2\text{O}_3\text{--SiO}_2$ or $\text{ZnO--Al}_2\text{O}_3\text{--SiO}_2$ system exhibit superior performances. Note that recently, low dielectric constant and low dielectric loss micro-nanostructured glass-ceramics, containing albite feldspars ($\text{NaAlSi}_3\text{O}_8$) with very low residual glass volume fractions ($< 6 \text{ vol}\%$), have been obtained by powder fast sintering methods (Fuentes *et al.*, 2018, 2019).

Glass-Ceramics Dielectrics for High Power Capacitors

The development of high energy storage density capacitors (HESDCs) requires materials able to withstand very high electric fields. Indeed, energy density w (J cm^{-3}) increases linearly with the dielectric constant ϵ_r and quadratically with the electrical field E :

$$\omega = \frac{\epsilon_0 \epsilon_r E^2}{2}$$

As previously mentioned, the advantage of glass over ceramics is the higher electrical strength. The drawback is their low dielectric constant. Crystallization of suitable phases in the glass can improve the dielectric constant (Letz *et al.*, 2014). This is for example the case in the $\text{Na}_2\text{O} - \text{PbO} - \text{Nb}_2\text{O}_5 - \text{SiO}_2$ glass system with the crystallization of NaNbO_3 preferentially to $\text{Pb}_2\text{Nb}_2\text{O}_7$ (Jun *et al.*, 2008). Precipitation of $\text{Ba}_x\text{Sr}_{1-x}\text{TiO}_3$ (BST) ferroelectric crystals is also widely investigated (Xiao *et al.*, 2016; Wang *et al.*, 2014). Commercial products such as Schott Poweramic™ are titanate-based glass-ceramics. However, when using the conventional crystallization process, the volume fraction of residual glass is often high and limits the final dielectric constant. Furthermore, due to their strong difference in dielectric constant, the interfaces between the residual glass and the crystals accumulate charges which leads to interfacial polarization (Pan *et al.*, 2006).

Pyroelectric/Piezoelectric Glass-Ceramics

Piezoelectricity results of the lack of a center of symmetry in the material. This excludes glasses and ceramics based on crystalline phases owning a symmetry center. Piezoelectric polycrystalline ceramics are usually ferroelectrics. For these materials, the random orientation of the crystals leads to a center of symmetry that can be broken by alignment of the crystal ferroelectric domains by applying an external electric field. This is not possible with non-ferroelectric phases that require either single crystals or textured polycrystals.

Piezoelectric glass-ceramics based on ferroelectric or non-ferroelectric phases have been investigated for a long time (Halliyal *et al.*, 1989; Davis *et al.*, 2008). Among the main ferroelectric phases crystallized are the perovskites BaTiO_3 , PbTiO_3 , LiNbO_3 , NaNbO_3 , widely encountered in ceramic materials (Wu and Zhu, 1986; Fernandes Graça and Almeida Valente, 2017). Contrary to ferroelectrics, the non-ferroelectric phases are less known and used. This is mainly due to their lower piezoelectric performances and the need to induce a significant preferential orientation of the crystals during the process. The piezoelectric charge coefficient d_{33} of ferroelectrics can reach several hundred pC/N, while non-ferroelectrics usually have a d_{33} around 10 pC/N. However, non-ferroelectric piezoelectrics are good candidates for applications at high temperature as they do not suffer from aging due to slow depoling over time and do not have a Curie temperature. Highly textured lead-free glass-ceramics based on the non-ferroelectric Sr-fresnoite $\text{Sr}_2\text{TiSi}_2\text{O}_8$ crystals can be obtained through surface crystallization (Halliyal *et al.*, 1985; Renoirt *et al.*, 2019).

Thermoelectric Glass-Ceramics

Thermoelectric (TE) materials show Seebeck and Peltier effects and consequently are able to directly convert heat into electrical power and reciprocally. Efficiency of a thermoelectric material is related to its figure of merit ZT given by:

$$ZT = \frac{S^2 T}{\rho \kappa}$$

With S the Seebeck coefficient, T the temperature, κ the thermal conductivity and ρ the electrical resistivity. A good thermoelectric material requires the maximization of the power factor S^2/ρ and the minimization of thermal conductivity κ . Moreover, the conversion efficiency increases with temperature. Conventional thermoelectric materials like Bi_2Te_3 or PbTe are environmentally harmful and use rare elements. In addition, their high-temperature stability is low.

Potential interest of thermoelectric glass-ceramics is based on the fact that the residual glass can hinder the thermal conductivity. However, residual glass volume fraction must be sufficiently low to allow 3D interconnectivity of the TE crystals. In addition, the crystallization process offers the possibility to synthesize nanostructured materials which can also be positive for the material properties. Various systems have been investigated such as the Sr-Ti-Nb-Si-B-O system with $\text{Sr}(\text{Ti,Nb})\text{O}_3$ crystals (Lingner *et al.*, 2013), Te-As-Se-Cu system with $\text{Bi}_{0.5}\text{Sb}_{1.5}\text{Te}_3$ (BST) crystals (Cui *et al.*, 2015), or Bi-Sr-Co-O system with $\text{Bi}_2\text{Sr}_2\text{Co}_2\text{O}_x$ crystals (Lingner *et al.*, 2015). Note that to achieve low residual glass fraction and then increase the electric conductivity, glass-ceramics can be prepared by spark plasma sintering (SPS) of a mix of glass powder and high TE phases.

Solid State Electrolytes for Rechargeable Batteries

Glasses and glass-ceramics are good candidates to develop low-cost rechargeable batteries based on safe solid electrolytes (Minami *et al.*, 2006). Glasses are good ionic conductors at high temperature due to the mobility of modifier cations. Conductivity of the cations is a function of the electronic configuration of the ions in the outermost orbital, and the ionic radius. The most favorable ions are Li^+ . Moreover, conductivity in sulfide glasses is higher than in oxide glasses. However, room temperature conductivity of these glasses remains too low to compete with organic electrolyte solutions used today in commercial Li-ion batteries.

Numerous works have highlighted an enhancement of Li^+ conductivity by controlled crystallization of the parent glass in a large range of systems such as $\text{Li}_2\text{S-P}_2\text{S}_5$ (Mizuno *et al.*, 2005; Xu *et al.*, 2016), $\text{Li}_2\text{S-P}_2\text{S}_5\text{-Me}$ ($\text{Me} = \text{SiS}_2, \text{GeS}_2, \text{SnS}_2, \text{Sb}_2\text{S}_3, \text{La}_2\text{S}_3, \dots$) (Liu *et al.*, 2014), $\text{Li}_3\text{BO}_3\text{-Li}_2\text{SO}_4$ (Tatsumisago *et al.*, 2017), or $\text{Li}_2\text{S-P}_2\text{S}_5\text{-X}$ ($\text{X} = \text{LiI}, \text{LiCl}, \text{LiBr}$) (Choi *et al.*, 2018). Room temperature ionic conductivity of the glass-ceramic $\text{Li}_{10}\text{GeP}_2\text{S}_{12}$ reaches $1.2 \cdot 10^{-2} \text{ S cm}^{-1}$, which is very close to that of liquid electrolytes (Kamaya *et al.*, 2011).

Fig. 14 Crack deflection by mica crystals in Macor[®] glass-ceramic. Reproduced from Grossman, D.G., 1978. Machining a machinable glass-ceramic. *Vacuum* 28, 55–61.

The use of sodium ions instead of lithium ions presents the advantage of lower cost and better availability of sodium sources. Sulfide glass-ceramics of the $\text{Na}_2\text{S}-\text{P}_2\text{S}_5$ system showing a sodium-ion conductivity of $2 \cdot 10^{-4} \text{ S cm}^{-1}$ at room temperature was achieved by stabilization of cubic Na_3PS_4 crystals with superionic conductivity (Hayashi *et al.*, 2012). As in the case of Li^+ solid electrolytes, a large range of glass compositions are under investigation, as for example $\text{Na}_2\text{S}-\text{P}_2\text{S}_5-\text{GeS}_2$ (Tanibata *et al.*, 2018). However, the conductivities are still two orders of magnitude lower than those of conventional liquid-electrolyte systems.

Note that most of the work published on this topic highlights the strong influence of the processing route on the structure and properties: melt-quenching, high-energy ball milling, solution synthesis method.

Machinable Glass-Ceramics

For some technical applications, it is necessary to obtain a precise shape. Generally, the easiest way to get the desired shape is to create it when the material is in the form of a glass, then to crystallize it into a glass-ceramic. However, if the desired shape is too complex, it may not be possible to obtain it in a glass form. Machinable glass-ceramics have therefore been developed to produce parts with specific and complex architectures. These glass-ceramics can be divided into two main families: mechanically machinable and chemically machinable. Note that some of them are also machinable using a laser.

Mechanical Machining

These glass-ceramics have specific mechanical properties that allow them to be precisely machined using ordinary and inexpensive cutting tools, without cracks or internal stress. As shown in Fig. 14, these glass-ceramics contain mica crystals which induce a house of cards microstructure which creates numerous interfaces acting as barriers for crack propagation. The damage induced by the machining is then confined to the residual glass and allows a tolerance of about $10 \mu\text{m}$. CAD/CAM techniques are mostly used, especially for dental applications (Thompson *et al.*, 1996; Gali, 2018).

MACOR[®] (Corning) contains fluorophlogopite mica crystals $\text{K}_{1-x}\text{Mg}_3\text{Al}_{1-x}\text{Si}_{3+x}\text{O}_{10}\text{F}_2$ and is a very versatile material that has been, and still is, a great commercial success. It is used in medical equipment, aerospace (e.g., retaining rings on doors, windows and hinges of space shuttles), electronic (e.g., high voltage insulators), lasers (e.g., spacers and reflectors), high vacuum (e.g., insulators), welding nozzles, and in the nuclear sector. Photoveel[®] (Sumikin Photon) is used in the electrical industry for its electrical and heat insulation properties. Vitronit[®] (Vitron Spezialwerkstoffe) shows high temperature resistance and electrical insulation capabilities. It is used in many fields such as welding technology and electrical engineering (Höland and Beall, 2012).

DICOR[®] (Corning/Dentsply) contains tetrasilic fluoromica crystals $\text{K}_{1-x}\text{Mg}_{2.5+x/2}\text{Si}_4\text{O}_{10}\text{F}_2$ and is used for dental restoration. It has an appearance and mechanical properties very similar to those of natural human teeth, and ceria is added to induce fluorescence (Li *et al.*, 2014). DICOR[®] is machinable through CAD/CAM. This technique can also be applied for Vitablocs[®] Marks II (Vita Zahnfabrik), IPS Empress[®] CAD (Ivoclar Vivadent) and IPS e.max[®] CAD (Ivoclar Vivadent).

Chemical Machining

Chemically machinable glass-ceramics are made by crystallizing a lithium silicate glass containing small amounts of photosensitizers such as silver and cerium oxide. Thanks to these additions, the glass becomes photosensitive (Borrelli, 2016). After forming the glass, localized UV irradiation is carried out on the areas to be removed as shown in Fig. 15. Note that other irradiation

Fig. 15 Etching process of photosensitive glass-ceramic. Reproduced from Dietrich, T.R., Ehrfeld, W., Lacher, M., Krämer, M., Speit, B., 1996. Fabrication technologies for microsystems utilizing photoetchable glass. *Microelectronic Engineering* 30, 497–504.

sources are explored such as X-rays (Imanieh *et al.*, 2008). After crystallization, the previously irradiated areas are chemically unstable due to the formation of Li_2SiO_3 . An etching (usually with HF) eliminates these areas, and a second crystallization creates chemically resistant $\text{Li}_2\text{Si}_2\text{O}_5$ crystals.

These materials are used to manufacture high-precision (μm) components. Fotoceram® (Corning Glass) contains Ce^{3+} as photosensitive ion and Ag^+ as nucleating agent. It is used for many applications including magnetic recording head pads, inkjet printer plates and fluidic devices. Foturan® (Schott) is widely used in microfluidics (e.g., printheads, lab-on-a-chip components), semiconductors (e.g., CMOS and memory modules), sensors, RF-MEMS (e.g., substrates, capacitors, and filters), and telecoms (e.g., optical waveguides). Foturan II® (Schott) allows a finer microstructure thanks to a better homogeneity of the photosensitive particles in the glass. APEX® Glass (3D Glass Solutions) is interesting for wafer-level packaging, RF packages (e.g., inductors and antennas), optoelectronics, and microcavities (Höland and Beall, 2012).

Laser Machining

A lesser known technique is the laser machining of glass-ceramics. It is used for radomes because their mechanical machining and polishing are quite long and expensive steps. Moreover, laser machining does not require the piece to be cooled down. This technique was also used to create blind holes in glass-ceramics used for cooktops (e.g., Ceran Suprema®, Schott) in order to place the temperature sensor as close as possible to the outer surface of the cooktop (Sola *et al.*, 2010). This laser machining does not modify the composition of the heat affected zone but decreases its mechanical properties. The laser machining of bioactive glass-ceramics is also under investigation for medical applications. To date, this shaping technique is rarely used but may be of interest in the implant and dentistry fields.

Glass-Ceramics From Wastes

Given the expansion of industrial activities, the amount of waste produced is constantly increasing. It is therefore necessary to recycle or isolate them. Creating glass-ceramics incorporating these wastes is interesting because the presence of crystals and a glassy phase allow some variations in the waste compositions, as opposed to typical ceramics which are very composition dependent. Two families of wastes must be distinguished: radioactive wastes and hazardous but non-radioactive wastes.

Fig. 16 Volatilization of waste radionuclides with temperature. Reproduced from Ojovan, M.I., Lee, W.E., 2014. *An Introduction to Nuclear Waste Immobilization*, second ed. London: Elsevier.

Radioactive Product Confinement

Radioactive wastes result from the reprocessing of spent nuclear fuels following their use in nuclear reactors and to a lesser extent, from medical and technical use of radioelements. Reprocessing (recovery of uranium and plutonium) releases fission products with a much shorter half-life than uranium, but which remains in the order of several hundred thousand years. They are called high-level wastes (HLW). They must therefore be isolated from the biosphere by incorporating them into durable matrices. Generally, borosilicate glasses are used for this application, but glass-ceramics can also be used and have better properties, especially mechanical properties (Ojovan and Lee, 2014). An important parameter is durability, i.e. the period during which it is possible to contain the radioactive elements without dangerous radiation escaping from the material.

Some of these glass-ceramics are obtained by the conventional processing route (i.e. melting and two step heat treatments for crystallization). This is the case for the following glass-ceramic compounds. The first system studied, $\text{SiO}_2\text{-Al}_2\text{O}_3\text{-B}_2\text{O}_3\text{-BaO}$, contains celsian $\text{BaAl}_2\text{Si}_2\text{O}_8$ as main phase along with pyrochlore $\text{RE}_2\text{Ti}_2\text{O}_7$, scheelite BaMoO_4 , pollucite $\text{CsAlSi}_2\text{O}_6$ and molybdenum-nosean $\text{Na}_8\text{Al}_6\text{MoO}_4(\text{SiO}_4)_6$. The $\text{SiO}_2\text{-TiO}_2\text{-Al}_2\text{O}_3\text{-B}_2\text{O}_3\text{-BaO}$ system, mainly containing fresnoite $\text{Ba}_2\text{TiSi}_2\text{O}_8$ as well as pyrochlore, scheelite and priderite $\text{BaFe}_2\text{TiO}_6\text{O}_{16}$, was also studied. However, these two systems did not have a higher durability than the glasses used at the time, even though their mechanical properties were higher. The $\text{Na}_2\text{O-Al}_2\text{O}_3\text{-CaO-TiO}_2\text{-SiO}_2$ system led to sphene CaTiSiO_5 glass-ceramics with no or almost no minor phases. Their mechanical properties and durability are high, and losses from volatile species (e.g., Cs, Mo, Na) are lower than those obtained when using borosilicate glasses. Fig. 16 shows the volatilization of main elements during glass melting that can be reduced using certain compounds (e.g., B_2O_3 or TiO_2 for Ce). The $\text{CaO-Al}_2\text{O}_3\text{-TiO}_2\text{-ZrO}_2\text{-SiO}_2$ system leads to crystallization of zirconolite $\text{CaZrTi}_2\text{O}_7$ along with some secondary phases such as pseudobrookite Fe_2TiO_5 , augite $(\text{Ca, Mg, Fe})\text{Si}_2\text{O}_6$ and cheykinite $\text{Ce}_4\text{Fe}_2\text{Ti}_3\text{SiO}_4\text{O}_{22}$. Glass-ceramics obtained from natural basalt were also used for waste immobilization, leading to the formation of many different crystalline phases due to the complex composition of basaltic rocks. These basaltic glass-ceramics can also be produced by crystallization immediately after casting the glass, a process described below that leads to other crystalline phases (Caurant et al., 2009; Donald, 2009).

Another way to synthesize a glass-ceramic is to crystallize it immediately after the melting step without returning to room temperature. This process leads to a lower manufacturing cost as glass-ceramics usually crystallize above 800°C . However, not all glass-ceramics can crystallize this way, as the maximum nucleation and crystallization rates must necessarily overlap (McCloy and Goel, 2017). Materials described hereafter are produced this way. Glass-ceramics based on diopside $\text{CaMgSi}_2\text{O}_6$, also containing powellite CaMoO_4 and perovskite CaTiO_3 , were produced and up to 30 wt% of waste can be incorporated. Their durability is higher than previously mentioned materials, so diopside glass-ceramics were the first candidates for immobilization of HLW. Some other crystalline phases can be obtained through this process using different compositions, such as apatite and powellite (Caurant et al., 2009; Donald, 2009).

Despite all the compositions developed, these glass-ceramics have not yet been implemented on a large scale because borosilicate glass is still preferred as its synthesis is well understood.

Fig. 17 Microstructural morphology of the VBA foams in the hardened state and after firing treatments (actual colors). Reproduced from Rincón Romero, A., Salvo, M., Bernardo, E., 2018. Up-cycling of vitrified bottom ash from MSWI into glass-ceramic foams by means of “inorganic gel casting” and sinter-crystallization. *Construction and Building Materials* 192, 133–140.

Toxic Wastes Disposal and Recovery

Toxic wastes include slags, ashes, dusts, sludges, incinerated wastes, and other hazardous but non-radioactive products released by various industries. The aim is to incorporate heavy (e.g., Pd, Cd, Hg) and toxic (e.g., As, Sb) metals into durable and if possible functional glass-ceramic matrices (Colombo *et al.*, 2003).

The synthesis of glass-ceramics incorporating slag from metallurgical processes has been extensively studied. At the end of the 1960s, Slagceram (GB) and Slagsital (USSR) were developed from these wastes for applications in the building industry. Many studies have been carried out using different waste compositions, nucleating agents and synthesis processes, leading to many different crystal phases (e.g., melilite, augite, lithium disilicate, diopside and wollastonite) (Rawlings *et al.*, 2006). In the late 1980s, Silceram glass-ceramics were developed and their properties allow their potential use in applications requiring resistance to thermal shock, erosion, impact and abrasion. Glass-ceramic floor tiles were also produced with 30 wt% slags (Dana and Das, 2003).

Coal fly ash is a waste produced when coal is burned to produce energy. Only a small part is used for cement production, so the glass-ceramic production is interesting for its reuse. Addition of CaCO_3 and TiO_2 lead to a glass-ceramic that can be used as a refractory material although its crystallization is long and happens at 1000°C (Cumpston *et al.*, 1992). A very esthetic material with good mechanical properties that looks like dark marble and malachite were proposed for building applications such as benches, walls or floor tiles (Leroy *et al.*, 2001). Glass-ceramics from the $\text{SiO}_2\text{--Al}_2\text{O}_3\text{--Li}_2\text{O}$ system were used to incorporate coal bottom ash. It may be used in cooktops, photolithographic processes and substrates for telescopes thanks to its low expansion coefficient. Foams for thermal insulation applications were also developed from coal fly ash and waste glass (Zhu *et al.*, 2016).

Municipal solid wastes are partly recycled, but some of them have to be incinerated, creating energy but also new wastes. Fly ash is recovered by air pollution control systems and contains mainly SiO_2 , CaO and Al_2O_3 . The presence of heavy metals (e.g., As, Hg, Pb, Sb, Sn) and organic pollutants makes isolation necessary (Kalogirou *et al.*, 2010). As glass-ceramics formed from these residues tend to crystallize from the surface, the sinter-crystallization process is mainly used. The main crystalline phases in materials synthesized from these wastes usually are diopside, wollastonite, ferrobustamite ($\text{CaO}_{1-x}\text{FeO}_x\text{SiO}_2$), gehlenite or augite. Glass-ceramics from municipal wastes were developed as promising materials for thermal energy storage for concentrating solar power (Py *et al.*, 2017).

Many other glass-ceramics have been synthesized from other wastes: copper and phosphorus slags, gasification process slags, electric arc furnace dust, cement dust, ore refining waste, fluorescent glass waste, sewage sludge, anodizing waste, hydrometallurgy waste, clay refining waste, and so on. Some foamed glass-ceramics that may be of interest for thermal insulation were also developed as shown in Fig. 17 (Wu *et al.*, 2005; Ding *et al.*, 2015; Xi *et al.*, 2018; Liu *et al.*, 2018).

Fig. 19 Glazes crystallized from the $\text{Li}_2\text{O}-\text{Na}_2\text{O}-\text{K}_2\text{O}-\text{CaO}-\text{Al}_2\text{O}_3-\text{SiO}_2$ system with addition of ZnO (Z series), TiO_2 (T series) and both (ZT series). Reproduced from Pekkan, K., 2015. The thermal and microstructural behavior of a $\text{R}_2\text{O}-\text{RO}-(\text{ZnO})-\text{Al}_2\text{O}_3-(\text{TiO}_2)-\text{SiO}_2$ based macro-crystalline raw glaze system. *Ceramics International* 41, 7881–7889.

Esthetic Materials

Some of the glass-ceramics listed in the previous section on waste recycling have sufficient mechanical properties associated with a good esthetic appearance which allow their use as building materials. Their use has been quite limited so far, which is certainly due to the apprehensiveness of using materials synthesized from hazardous waste, despite their immobilization.

There are also commercial glass-ceramics that combine good mechanical properties with good esthetics. Neopariés® (Nippon Electric Glass) is the most commonly used material, especially for large interior and exterior walls (see Fig. 18). It can be produced

as flat or curved plates, and its color can be easily changed (Marangoni *et al.*, 2017). It contains wollastonite crystals, as well as Cryston® (Asahi Glass) which is used as cladding material. Transparent glass-ceramics containing β -quartz crystals such as Éclair® (Eurokera) and Firelite® (Nippon Electric Glass) are not only used for decoration but also in fire-resistant windows.

A glaze is the application of a glass to the surface of a ceramic object or tile to increase its resistance to the environment or to improve its esthetic properties. This technique has existed since 1000 BCE, so many colors and shades have been developed over time by adding different additives to the glass and by changing the annealing temperatures. However, since the 1990s, higher abrasion resistance, hardness, and chemical resistance have been required. Glass-ceramic glazes (also called crystalline glazes) were then developed to meet these requirements. The crystalline phases most often found in glass-ceramic glazes are zircon (ZrSiO_4), anorthite ($\text{CaAl}_2\text{Si}_2\text{O}_8$), wollastonite (CaSiO_3), celsian ($\text{BaAl}_2\text{Si}_2\text{O}_8$), leucite (KAlSi_2O_6), cordierite ($\text{Mg}_2\text{Al}_4\text{Si}_5\text{O}_{18}$) and mullite ($\text{Al}_6\text{Si}_2\text{O}_{13}$). High concentrations of TiO_2 and Fe_2O_3 lead to the crystallization of rutile and hematite respectively as they precipitate during cooling of the glass. Small variations of composition can lead to very different visual effects as shown in Fig. 19. Some glass-ceramic glazes also show specific properties, such as photocatalytic activity for self-purification of their environment, aventurine effect caused by macroscopic crystals giving a sparkling effect to the glaze, or metallic aspect without using toxic and heavy compounds (Casasola *et al.*, 2012).

Introduction

Compared to crystalline ceramics, glasses feature a distinctive advantage in the possibility of sintering at just moderately high temperatures (Mackenzie and Shuttleworth, 1949; Prado *et al.*, 2001; Olevsky *et al.*, 2006; Wadsworth *et al.*, 2016). In fact, glass powders may coalesce and form a ‘pyroplastic’ mass once put above the so-called dilatometric softening point, in turn placed slightly above the transition temperature, T_g (Rawson, 1980). At this specific temperature, the thermal expansion of a piece of softened glass is exactly counterbalanced by its contraction – due to viscous flow –, under axial compression, induced by the same dilatometric equipment (in a typical push rod dilatometer, pieces are placed in heated chamber and they are pressed by means of a ceramic connecting rod, which transfers the expansion to a strain gauge; Sighinolfi, 2010; Tian *et al.*, 2013).

It is evident that the dilatometric softening point – corresponding to a viscosity of $10^{11.5}$ Pa s (Rawson, 1980) – actually represents a minimum temperature for glass sintering, that could be adopted in hot pressing operations (Bernardo *et al.*, 2006), where the viscous flow is enhanced by much more intense mechanical load, compared to that operated by a dilatometer. An optimum temperature for pressure-less glass sintering could be estimated as 50–100°C above the dilatometric softening temperature (Ray and Tiwari, 2001), still well below “Littleton” softening point, corresponding to gross viscous flow, for a viscosity of approximately $10^{6.6}$ Pa s (Rawson, 1980). In other words, powder compacts, once fired at the optimum temperature, turn into a nearly pore-free body, with a homogeneous shrinkage. The final component may exhibit an excellent retention of the geometry of the “green” body, except for the size reduction, in case of good initial particle packing and simple shape (for complex three-dimensional features, such as internal voids, cantilevers, overhangs, glass sintering is not actually “pressureless”, since gravity is no longer negligible; Andreev and Zakharov, 2012, 2014). Even very simple shapes are lost in case of “overfiring”, i.e., sintering at excessively high temperatures; glasses with an abrupt reduction of viscosity with increasing temperature (“short” glasses, e.g., featuring a short temperature interval between viscosity values of 10^4 and 10^8 dPa s, as reported by Karamanov *et al.*, 2002), are obviously more delicate.

Contactless optical dilatometers offer a simple way to assess the sintering of ceramic powder compacts, with increasing temperature, according to any firing schedule, without any applied pressure (dimensional changes are detected by means of light beams, detected by high resolution image sensors; Paganelli, 2002; Sighinolfi, 2010); applied to glasses, optical dilatometry provides evidence of the optimum sintering temperature, with shape retention (Karamanov *et al.*, 2013). Interestingly, being contactless, i.e., not interfering with the sintering process, the apparatus gives an excellent representation of some reactions occurring upon viscous flow sintering, e.g., those leading to more or less significant expansion of samples, by gas release, such as “bloating” of traditional ceramics or “foaming” of cellular glasses (Gualtieri, 2007; Teixeira *et al.*, 2017).

The reactions occurring upon glass sintering must be defined carefully. The present paper aims at providing the most important and most recent findings concerning viscous flow sintering of glass accompanied by *reactions with a significant impact on the chemistry and on the phase assemblage* of the resulting glass-based product. The distinction is not trivial, especially in cellular glasses.

Glass foams probably represent the most appreciable evidence of the advantages of glass sintering, at moderate temperatures (850–1000°C), compared to glass melting (>1400°C). In fact, the first procedures for the manufacturing of foams (dating back to nearly one century ago), relying on gas bubbling in molten glass, were successfully replaced by glass sintering with concurrent gas evolution from selected additives (foaming agents), thus offering a fundamental up-cycling option for waste glasses (Scarinci *et al.*, 2005). When operating with fully thermally degradable additives, such as carbon (carbon black, graphite) or organic compounds, the pyroplastic mass of softened glass is expanded by formation of carbon monoxide and/or carbon dioxide, ideally with no impact on glass chemistry. However, the commercial production of glass foams actually involves intensive chemical interaction between glass and foaming agents, since the oxygen used for CO/CO₂ generation does not simply derive from an oxidative atmosphere, but also from the reduction of manganic and ferric oxides dissolved in a specifically formulated glass (in turn mixed with waste glass), for the sake of homogeneity (Scarinci *et al.*, 2005).

In many other cases the foaming agent is not completely degraded, so that residues are incorporated in the pyroplastic mass (e.g., SiO₂ from the oxidation of SiC, CaO from the decomposition of CaCO₃), and they may promote some crystallization (e.g., formation of wollastonite, CaSiO₃, from CaO/glass interaction; Scarinci *et al.*, 2005). To summarize, glass foams, in most cases, are properly products of a glass reactive sintering process; they may be excluded just considering the low *quantity* of interactions, in turn due to the limited amount of additives (typically well below <5 wt%).

Glass-Ceramics From Sinter-Crystallization: What Reaction?

A strict definition of glass-ceramics corresponds to the availability of a homogenous glass, in the form of powders or bulk pieces, in a first step. In a second step, when put above T_g , glass turns into a metastable super-cooled liquid, that may transform in a (at least) partially crystallized solid, by relatively long holding times at temperatures at which nucleation and crystal growth are maximized, before final cooling. The second step is often termed as “ceramization” (Höland and Beall, 2012; Pannhorst, 1997). According to this definition, the so-called ‘petrurgic process’ (applied since the 1970s, e.g., in the so-called “Silceram” ceramics, deriving from molten metallurgical slags; Rawlings *et al.*, 2006), should not be treated as a glass-ceramic manufacturing process, since it consists of the controlled cooling of a silicate melt, typically (but not exclusively) with a long intermediate temperature holding stage, at which crystals nucleate and grow. The process evidently resembles the crystallization of natural rocks (Francis *et al.*, 2002), but it keeps, from glass-ceramics, the idea of fine tuning of microstructures by engineering of heat treatment conditions, particularly the cooling rate (from 1 to 10°C/min).

With the sinter-crystallization process, the transformation of glass into a partially crystallized material, i.e., a *physical* reaction, overlaps with viscous flow sintering. Compared to the processing of bulk glass pieces, sinter-crystallization offers advantages in terms of quality and reduction of overall cost. In fact, any defect in a bulk piece of glass (e.g., gas bubbles from vitrification reactions) remains in the glass-ceramic body, after ceramization, so that high quality, pore-free glass-ceramic articles (like cooking tops, radomes, magnetic disc substrates etc.; Höland and Beall, 2012) are obtained only after high quality glass processing. A long and expensive refining step is required for bulk pieces; powdered glass, on the contrary, is assumed to be pore free. A second occasion of cost saving comes from the simplified ceramization, mostly occurring by a single step treatment at the sintering temperature. A high degree of crystallization may be achieved in very short times, since the surface of glass powders is a preferred site for nucleation, even in the absence of nucleating agents (Müller *et al.*, 2000; Prado and Zanotto, 2002; Francis *et al.*, 2004; Hernández-Crespo *et al.*, 2006). In selected cases (“fast sinter-crystallization”), the holding time may not exceed 30 min, at the end of a very fast heating step (a “direct heating”), e.g., the insertion of glass powder compacts in the furnace directly at the sintering temperature, is also possible, as shown by Bernardo (2008).

Main Fields of Application

In general, there are three fundamental application fields for sinter-crystallization, such as:

- (1) Materials for (bone) tissue engineering.
- (2) Ceramic-metal and ceramic-ceramic joining.
- (3) Waste-derived construction materials.

The following sub-sections will be dedicated to the key aspects of the applications.

Sintered glass-ceramics in biomedical applications

The use of glass-ceramics in bone tissue applications dates back to 1970s. At that time, the huge bioactivity potential of bioglasses, namely Hench’s 45S5 bioglass (nowadays a sort of “golden standard” for bioceramics) had been already disclosed (Piotrowski *et al.*, 1975; Hench, 1977, 2006). An improvement of mechanical properties (i.e., strength, toughness, hardness), generally determined by the transformation of glasses into glass-ceramics, coupled with the bioactivity of silicate and phosphate crystal phases, motivated the research on glass-ceramics, including those from surface crystallization of powdered glass (Gerhardt and Boccaccini, 2010; Montazerian and Zanotto, 2016). The improvement of mechanical properties, compared to parent glasses, is not important just in the perspective of load-bearing implants, but also in terms of easy machinability and workability, particularly appreciated in dental applications (Albakry *et al.*, 2004; Höland *et al.*, 2007; Höland and Rheinberger, 2008).

Kokubo’s apatite-wollastonite and Biosilicate® glass-ceramics are fundamental examples of sinter-crystallized “bio-glass-ceramics”. The first is significant for the attempt to produce a glass-ceramic with a crystal phase (apatite) presenting obvious similarities with the mineral fraction of bone (oxyfluoro-apatite in the glass-ceramic, hydroxyl-apatite in natural bone) and acting as Ca^{2+} reservoir for new bone (Kokubo *et al.*, 1982; Hench and Kokubo, 1998). The second is interesting in highlighting the potential of slight compositional changes, in tuning the crystallization/bioactivity balance, in glasses deriving from 45S5 (Filho *et al.*, 1996; Peitl *et al.*, 2001; Crovace *et al.*, 2016; Pinto *et al.*, 2018).

A quite well recognized drawback of 45S5 concerns the processing. When subjected to viscous flow sintering, it easily undergoes crystallization, with degradation of the bioactivity. Li *et al.* (1992), as an example, showed that the in vitro formation rate of a hydroxycarbonate apatite layer (HCA) on the surface of a 45S5 bioactive glass decreased with increasing crystallization degree. This observation was the starting point for a revision of formulations, in turn leading to “bioglasses resisting crystallization” upon sintering (Souza *et al.*, 2017; Bellucci and Cannillo, 2018; Bellucci *et al.*, 2018), including bioglass 13–93 (Kolan, *et al.*, 2011; Liu *et al.*, 2013; Motealleh *et al.*, 2019), from one hand, and to “bioglasses with enhanced bioactivity after crystallization”, on the other. The second class actually refers to more recent observations, according to which HCA formation could be delayed, but not entirely inhibited, by reducing the amount of residual glassy phase (Moura *et al.*, 2007; Zanotto, 2010). A number of in vitro, in vivo and clinical studies have shown that the osteoconductivity, osteoinductivity, biocompatibility, and antibacterial

properties, exhibited by nearly fully crystallized Biosilicate® glass-ceramics, are comparable to those of amorphous 45S5 (Crovace *et al.*, 2016; Pinto *et al.*, 2018).

45S5 practically turns into Biosilicate® after minor corrections of the proportions between Na₂O, CaO, SiO₂ and P₂O₅ (23.75 wt% Na₂O, 23.75% CaO, 48.5% SiO₂ and 4% P₂O₅ for Biosilicate®, against 24.5 wt% Na₂O, 24.5% CaO, 45% SiO₂ and 6.0% P₂O₅ for 45S5) (Hench, 2006; Granito *et al.*, 2009). Like in Kokubo's glass-ceramics, the crystallization yields a silicate and a phosphate phase (Na₂CaSi₂O₆ and NaCaPO₄); depending on the heat treatment conditions, however, the phosphate phase may be formed (2P variant) or not (1P variant) (Crovace *et al.*, 2016; Pinto *et al.*, 2018).

Several research groups are currently active in the “engineering of crystal phases” of bioactive glass-ceramics. Highly soluble calcium silicates, as an example, may be replaced by calcium-magnesium silicates such as diopside (CaMgSi₂O₆) and akermanite (Ca₂MgSi₂O₇), which dissolve less rapidly in the human body, but exhibit higher strength (Juraski *et al.*, 2017). CEL2 glass-ceramics (belonging to the SiO₂-P₂O₅-CaO-MgO-K₂O-Na₂O system; Vitale-Brovarone *et al.*, 2009) and alkali-free glass-ceramics (based on CaO-MgO-SiO₂-P₂O₅-CaF₂ system; Goel *et al.*, 2011) provide excellent examples.

Some crystal phases exhibit an intrinsic flexibility in hosting several ions, in turn allowing a fine tuning of biological response: Zreiqat and coworkers, as an example, introduced glass-ceramics based on hardystonite - Ca₂ZnSi₂O₇ (Roohani-Esfahani *et al.*, 2013, 2016; Li *et al.*, 2019) -, belonging to the same mineral group (“melilites”) of the previously mentioned akermanite. The crystal structure, comprising of Ca²⁺ ions sandwiched between Zn(Si₂O₇)⁴⁻ sheets, leads to many solid solutions, by replacement of Ca²⁺ (e.g., with Sr²⁺), as well as by modifications in the sheets (e.g., with Mg²⁺ instead of Zn²⁺) (Kaminskii *et al.*, 1986; Giuli *et al.*, 2000; Chihara *et al.*, 2007; Joseph and Sebastian, 2010; Wu *et al.*, 2014; Warren, 2015). Most of hardystonite bioceramics actually derive from the sintering of crystalline powders previously prepared the sol-gel method (Wu *et al.*, 2005, 2008; Wu and Chang, 2013); hardystonite-yielding glasses are typically obtained by deviation from the stoichiometry of the silicate, resulting in the precipitation of a secondary, biologically inert, crystalline phase, such as gahnite (ZnAl₂O₄), according to the presence of Al₂O₃ (Roohani-Esfahani *et al.*, 2013).

Most glass-ceramic systems are exploited for the manufacturing of highly porous scaffolds, according to different fabrication techniques, including replica of sacrificial PU sponges (Baino and Vitale-Brovarone, 2012; Roohani-Esfahani and Zreiqat, 2012; Desimone *et al.*, 2013; Baino and Vitale-Brovarone, 2014), direct foaming of glass suspensions (undergoing progressive gelation, owing to organic or inorganic binders) (Sepulveda and Binner, 1999; Conzenbach *et al.*, 2007) and, more recently, additive manufacturing technologies, such as direct ink writing or “robocasting” (Eqtesadi *et al.*, 2014; Ben-Arfa *et al.*, 2019), powder-based 3D printing and stereolithography, starting from fine powders and sacrificial organic binders (Thavorniyutikarn *et al.*, 2017; Schmidt *et al.*, 2018; Elsayed *et al.*, 2018a, 2019a).

The delicate balance of viscous flow and crystallization acts as further tuning parameter. On the one hand, the viscous flow may determine the filling of voids, left in the struts of open-celled foams from the replica technique, left by the burn-out of the polymer template at the early stages of sintering; dense struts obviously favor the mechanical properties (Vitale-Brovarone *et al.*, 2009). On the other hand, crystallization is useful in “freezing” the viscous flow, so that macro-pores from “primary shaping” (i.e., printing, foaming) are not substantially altered (except for some shrinkage) and they may be accompanied by a multitude of micron-sized pores, from incomplete densification, favouring cell attachment and infiltration of body fluids (Elsayed *et al.*, 2017a).

Fig. 1(a) provides an example of highly porous scaffold (Kelvin cell architecture) from digital light processing of a glass corresponding to the stoichiometry of a Sr-Mg containing hardystonite solid solution (Ca_{1.4}Sr_{0.6}Zn_{0.7}Mg_{0.3}Si₂O₇): the high crystallization tendency of stoichiometric glass (upon firing at 100°C) effectively leads to micro-porous struts (Fig. 1(b)).

Glass-ceramic joints

One of the most interesting applications of sintered glass-ceramics is represented by the use as sealants for the fabrication of solid oxide fuel cells (SOFCs) and solid oxide electrolysis cells (SOECs), for clean energy production. Sandwiched between the metallic

Fig. 1 Low magnification (a) and high magnification (b) details of a glass-ceramic scaffold from digital light processing of a glass based on a Sr-Mg hardystonite solid solution.

interconnect (classically comprising a ferritic stainless steel), and the ceramic electrolyte (typically yttria stabilized zirconia), glass powder densify and from a semi-crystalline continuous joint, by sinter-crystallization (Mahato *et al.*, 2015).

A distinctive character of SOFCs/SOECs is that the thermal treatment used for the manufacturing is not a final step, since the obtained products are employed at high temperatures, typically from 650 to 800°C, under oxidizing and reducing environments. Mechanical degradation, as well as volatilization and diffusion of the components, must be carefully prevented, in order to preserve gas-tightness and high electrical resistivity ($> 10^3 \Omega \text{ m}$), according to Rodríguez-López *et al.*, 2016.

The crystallization during sintering is interesting for achieving strong joints, but it is conditioned by several constraints. In fact, the coefficient of thermal expansion (CTE) of glass-ceramic joint must be quite close to that of adjoining parts, to minimize thermal stresses, upon cyclic operation (Rodríguez-López *et al.*, 2017; Javed *et al.*, 2018). The developed phases should remain stable upon time, to prevent variations in CTE and degradation of the self-healing effect, consisting of the relaxation of stresses operated by the softening of quite abundant residual glass phase. Alkali-containing formulations are undoubtedly interesting for achieving joints with high CTE (above $9 \cdot 10^{-6} \text{ K}^{-1}$), but they are also delicate in terms of excessive electrical conductivity (Chou *et al.*, 2011). Interestingly, the previously mentioned Ca-Mg silicates (namely diopside) are included among the crystal phases in glass-ceramic sealants (Sabato *et al.*, 2019); glass-ceramics from alkali-free formulations, based on Ba and Sr silicates (exhibiting high CTE values), were also proposed (Kaur *et al.*, 2012).

The characteristic ability of softened glass to adhere on oxide and/or oxidized surfaces is at the basis of the development of glass-ceramic joints in other fields, including sodium-based batteries (Song *et al.*, 2011; Smeacetto *et al.*, 2017) and, above all, numerous ceramics, such as SiC, Al_2O_3 and yttria-stabilized zirconia (Smeacetto *et al.*, 2009; Reddy *et al.*, 2013; Zhu *et al.*, 2013; Herrmann *et al.*, 2014; Döhler *et al.*, 2017; Sun *et al.*, 2019; Akram *et al.*, 2019).

Sintered glass-ceramics for building applications

Sinter-crystallization is appreciable also for the special optical properties of some products, which can be used as cladding in the building industry, as a valuable alternative to natural stones, such as marble and granite (Höland and Beall, 2012), starting from the well-known Neoparies[®], produced and marketed by Nippon Electric Glass Co. Ltd since 1970s.

Glass-making and subsequent “ceramization” are obviously expensive, but the manufacturing of glass-ceramics does not compromise natural landscapes (as in the case of quarrying, Pelekasi *et al.*, 2012), with the fundamental advantages of far superior mechanical properties and durability of the products. $\text{CaO-Al}_2\text{O}_3\text{-SiO}_2$ glasses, even in the absence of conventional volume nucleation agents (such as TiO_2 and ZrO_2), are converted into wollastonite glass-ceramics by sintering of coarse glass granules (1–7 mm) at 950–1000°C (Höland and Beall, 2012). A surface-induced nucleation determines the formation of wollastonite crystals at the boundaries of former glass granules (reshaped and glued by viscous flow), successively growing towards the center (upon heating at 1100°C), in the form of many thin needles. The distinctive marble-like appearance derives from differential light scattering occurring at highly crystallized boundaries and less crystallized cores of former glass granules (Höland and Beall, 2012).

The concept of Neoparies[®] has been a reference for many “waste-derived glasses” (Gutzow *et al.*, 1998). With the specific term we do not refer to glasses which are not usable, fully or partially, in the manufacturing of the original articles (“waste glasses”, mentioned before), but we denote glasses deriving from the dissolution of several inorganic residues (slags, ashes, mining tailings, etc.) in a homogeneous melt, cooled down avoiding crystallization (Rincón Romero *et al.*, 2016). When properly formulated, these glasses offer a complete stabilization of hazardous pollutants, such as heavy metals (Colombo *et al.*, 2003); in some cases, waste stabilization does not depend on the embedding of hazardous ions in the glass structure, but on the thermal destruction (e.g., dismantling of the characteristic, and highly hazardous, fibrous structure of asbestos-containing waste) (Rincón Romero *et al.*, 2016). The high costs of plants and the energy consumption, in waste vitrification, have been compensated, besides by avoided disposal costs, by the extra revenue from glass-ceramic building materials, since the early 1960s, i.e., soon after the discovery of the very first glass-ceramics, by Stookey, in 1953 (Höland and Beall, 2012; Rincón Romero *et al.*, 2016). The manufacturing of glass-ceramics is actually the most established valorization way for inorganic waste, as supported by an extremely vast literature (Colombo *et al.*, 2003; Rawlings *et al.*, 2006; Chinnam *et al.*, 2013; Rincón Romero *et al.*, 2016), and by extensive industrial production, under trade names such as “Slagsittals”, “Slagceram” and the previously cited “Silceram” (Rawlings *et al.*, 2006; Höland and Beall, 2012).

In the specific field of waste-derived glass-ceramics, sinter-crystallization provides valid solutions for usual drawbacks, such as the control of defects and the visual appearance. As previously mentioned, high quality glass-ceramics from bulk crystallization need high quality glass preforms, obtained by means of extensive refining of the glass melt. This operation may be difficult with waste-derived glasses, where heavy metals determine a dark coloration and a consequently poor radiative thermal conduction. Extensive refining, in addition, brings risks of corrosion of refractories in glass tanks and evaporation of some hazardous volatile components (e.g., PbO). The pleasant marble-like appearance of Neoparies[®] is reproduced in waste-derived materials, even at a finer scale, starting from powders $< 100 \mu\text{m}$, leading to nearly pore-free tiles, after uniaxial pressing and firing, needing limited machining (Rincón Romero *et al.*, 2016).

Highly porous construction materials, for thermal and acoustic insulation, deserve a specific discussion. As mentioned in the introduction, glass foams are substantial examples of glass sintering; more precisely, they mostly derive from the coupling of viscous flow and gas evolution, from decomposition or oxidation reaction of selected additives, mixed with glass powders. A significant expansion occurs if the additive is activated at a temperature at which the glass viscosity is a specific range $10^{3.3}\text{--}10^6 \text{ Pa s}$ (Petersen *et al.*, 2017); high viscosities hinder the expansion, whereas low viscosities determine the coarsening and the collapse of the cellular structure (Scarinci *et al.*, 2005). The sudden increase of viscosity operated by crystallization complicate the obtainment

of glass-ceramic foam by direct sintering (Hasheminia *et al.*, 2012); high strength semi-crystalline foams were reported from mixtures of glasses not prone to crystallization (e.g., soda-lime glass) and glasses undergoing crystallization (Bernardo *et al.*, 2010a; Chen *et al.*, 2019), according to a more extensive reactive sintering (discussed in a following section).

The direct foaming of glass aqueous suspensions, mentioned for the production of bioactive glass-ceramic scaffolds, provides a valid alternative, in handling glasses undergoing crystallization without additives. Foamed structures are formed at low temperature, according to intensive mechanical stirring (with the help of surfactants) of suspensions subjected to progressive hardening, before consolidation by sinter-crystallization. Recent investigations have highlighted the hardening of glass suspensions by weak alkali activation, i.e., by formation of surface gels, in turn formed by partial dissolution of glass powders. Highly porous glass-ceramics may reach excellent strength-to-density ratios (strength exceeding 6 MPa, with open porosity of ~80 vol%; Rincon Romero *et al.*, 2018).

Sinter-Crystallization Aided by Chemical Reactions

The sinter-crystallization of waste-derived glasses derives from a quite complicate interaction between viscous flow and crystallization, activated by surfaces but also by specific components, such as iron oxides, acting as nucleating agents. Iron oxides actually configure a condition of “sintering-reaction-crystallization”, since a *chemical* interaction overlaps with viscous flow and crystallization. In fact, magnetite (Fe_3O_4 , or $\text{FeO} \cdot \text{Fe}_2\text{O}_3$), i.e., iron oxide with iron ions in mixed oxidation state ($\text{Fe}^{2+}/\text{Fe}^{3+}$), is a powerful nucleating agent, but its formation from waste-derived glasses depends on vitrification conditions (chemistry of the system controlled *a priori*) and/or sintering conditions, i.e., chemical interaction with the firing atmosphere (chemistry of the system controlled *a posteriori*). On the one hand Karamanov *et al.* (2000) observed that the addition of C (1.5%–2%) to the glass batch promoted the separation of magnetite and enhanced the crystallization, upon sintering. On the other hand, Liu *et al.* (2015) found that iron oxidation, causing an increase of viscosity, reduced the crystal growth of silicates; this fact could be prevented by applying sintering in inert (N_2) or reactive (CO) atmosphere. Bernardo *et al.* (2009a), starting from a glass with a low $\text{Fe}^{2+}/\text{Fe}^{3+}$ ratio, observed that magnetite was promoted by oxidation, in turn more pronounced for fine ($<40\ \mu\text{m}$) than for coarse glass powders ($<80\ \mu\text{m}$).

The concept of glass sintering with concurrent chemical interaction between softened glass and atmosphere has been exploited beyond waste-derived glasses. Chenu *et al.* (2012, 2016), as an example, presented glass reactive sintering as a tool for the synthesis of NZP glass-ceramics. NZP phases consist a class of fast ion conductors, named after the most representative member, $\text{NaZr}_2(\text{PO}_4)_3$. A number of solid solutions is feasible, according to the many possibilities of ionic substitutions; however, NZP monoliths are hardly achievable by means of solid state sintering, at temperatures exceeding 1000°C . When operating with a sodium phosphate glass, including SnO and WO_3 , NZP phase containing tungsten (IV) and tin (IV), could be achieved by the sintering of powders, at a temperature not exceeding 750°C . In air or oxygen atmosphere, glass particles undergo sintering with concurrent oxidation reaction, in turn triggering the crystallization of the desired NZP phase.

Glass-Ceramics From Extensive Reactive Sintering

In the previous paragraph we discussed cases of limited chemical interactions occurring upon sintering. The sintering of a glass with additives gives excellent opportunities for mixing at a quasi-molecular level; in other words, additives bring oxides that are dissolved in the pyroplastic mass determined by viscous flow sintering, with dramatic effects on phase evolution. In general, additives consist of secondary glasses or reactive oxides, in the form of powders or precursors; in latter case, very recent investigations focused on reactive binders, e.g., additives contributing to both shaping of glass powders and chemistry of the final ceramic, considering the not negligible ceramic residue left upon heat treatment.

Sintered Glass-Ceramics From Mixtures of Glasses

As stated above, sinter-crystallization corresponds to a delicate balance between viscous flow and crystallization. It has been widely shown that a good densification, with remarkable crystallization, may be achieved, from fine glass powders ($<40\ \mu\text{m}$) (Bernardo *et al.*, 2009a), by a single step firing treatment just at the crystallization temperature (inferred from an exothermic peak in the DTA plot), once placed suitably above the dilatometric softening point. With limited gaps between the two temperatures, the sudden enhancement of glass viscosity operated by crystal precipitation complicates the sintering; improvements in the densification may be obtained by forcing the viscous flow, i.e., increasing the firing temperature and/or the heating rate (Bernardo *et al.*, 2009b). An interesting alternative is represented by the mixing of waste-derived glass with waste glass, e.g., material from dismantled containers. A new glass-ceramic, from the simultaneous sintering of two glasses, may be manufactured without correcting the formulation of the waste-derived glass, from industrial plasma vitrification of municipal solid waste incinerator fly ash (Bernardo *et al.*, 2010b).

Soda-lime or pharmaceutical boro-alumino-silicate container glass are poorly sensitive to crystallization, so that they could be introduced, mixed with waste-derived glass, to offer extra softened material, keeping its flowing ability in any stage above T_g , upon firing (unlike softened waste-derived glass, undergoing crystallization). Their role as “sintering aid” for waste-derived glasses,

Fig. 2 Obtainment of a highly porous glass-ceramic from a semi-crystallized residue mixed with soda-lime glass.

however, does not simply correspond to the dilution of the material which is more sensitive to crystallization (useful, as previously mentioned, for the manufacturing of semi-crystalline foams). In other words, the softened extra glass does not simply fill the voids left by inadequate sintering of waste-derived glass, but it causes a complex chemical interaction. The phase assemblage is reshaped, as an effect of the ionic interdiffusion at the interface between different glasses: silica-poor crystal phases, such as melilite solid solutions (e.g., gehlenite, $\text{Ca}_2\text{Al}_2\text{SiO}_7$), are replaced by silicates (wollastonite and pyroxene solid solutions) and silica-rich aluminosilicates (e.g., anorthite, $\text{CaAl}_2\text{Si}_2\text{O}_8$) (Bernardo *et al.*, 2010b).

Since the reshaping of the phase assemblage has consequences on the chemical formulation of the residual glass phase, the addition of a secondary glass may improve the stabilization of pollutants included in waste-derived glasses (Monich *et al.*, 2018). Finally, if we consider the obtainment of porous glass-ceramics from mechanical stirring (“frothing”) of alkali activated suspensions of glass powders, the secondary glass may improve the gelation. Fig. 2(a) shows the microstructure of a foam from a partially crystallized glass-based residue from plasma vitrification of asbestos-containing waste (Europlasma Inertam, Bordeaux, France), combined with soda-lime glass (30 wt%) (Authors’ unpublished results). The addition of soda-lime glass allowed the gelation of a suspension with low alkalinity (1 M NaOH). Fig. 2(b) shows the above-mentioned reshaping of phase assemblage upon sintering at 900°C: akermanite and pyroxene, dominant in the as-received residue, were partially dissolved, with enhanced precipitation of wollastonite.

Direct Sintering of Waste-Derived Glass-Ceramics

Waste glasses (less properly termed “recycled glass”) have a fundamental role in the management of inorganic waste, well beyond their use as sintering aids. In fact, the ultimate strategy for energy and cost savings, in waste vitrification, quite paradoxically consists of avoiding the same process (Rincón Romero *et al.*, 2016). Especially operating with waste with limited hazardousness, the inclusion of pollutants in a chemically stable glass matrix may be performed just letting the waste dissolve, at least partially, in the pyroplastic mass offered by common glasses. This constitutes the basis for the so-called glass-ceramics from “direct sintering” (Rawlings *et al.*, 2006; Valderrama *et al.*, 2019).

The effectiveness of chemical interaction is essential, since it denotes the transition from glass matrix composites, in which oxides remain *physically* dispersed in a glass matrix (e.g., in the case of Al_2O_3 plate-like monocystals, the brittleness of the matrix is reduced owing to crack deflection at glass/reinforcement interfaces; Boccaccini and Trusty, 1996; Boccaccini and Winkler, 2002) and glass-ceramics. Glass-ceramics from direct sintering, although there is no stage in which the starting raw materials are mixed and converted into a homogeneous glass, are generally accepted as a variant of sintered glass-ceramics, owing to the generally observed phase evolution (Rawlings *et al.*, 2006; Rincón Romero *et al.*, 2016; Valderrama *et al.*, 2019). Waste glasses, besides promoting the densification by viscous flow sintering, react with oxides from inorganic waste, leading to silicate and aluminosilicate crystals similar to those developed by glass devitrification.

Direct sintering finds analogies in the processing of traditional porcelain ceramics. In porcelain and in porcelain stoneware some components (feldspar minerals) melt and form a liquid phase (at 1100–1200°C), incorporating residues from the others (quartz and clay minerals). Silica from the transformation of clays and from quartz is dissolved in the liquid provided by feldspars, cooling into a glass phase, in turn hosting mullite crystals, from the same transformation of clays, and un-reacted quartz crystals (Sánchez *et al.*, 2010). In directly-sintered glass-ceramics, waste glasses offer the fluxing action of feldspars at much lower temperature (1000°C) and host crystals, from thermal transformations of inorganic waste (e.g., decomposition of fayalite, Fe_2SiO_4 , in slag from copper metallurgy, as shown by Ponsot *et al.*, 2014) as well as from glass/waste interactions and also from glass/clay interactions (when clay minerals are added as binders in glass/waste mixtures, as reported by Bernardo *et al.*, 2009c).

Low temperature treatments, instead of vitrification, may be useful to stabilize selected pollutants. As an example, F-containing waste (Ponsot *et al.*, 2013), once included in directly sintered glass-ceramics, do not undergo decomposition reactions that would lead to evolution of fluorine. In general, however, directly sintered glass-ceramics evidently lack homogeneity, so that some pollutants may selectively accumulate in regions not completely dissolved in the liquid phase provided by the glass component. In addition, the residual porosity (in the order of 30%–35%) and the water absorption could be far above those of real sinter-crystallized glass-ceramics, natural stones and even traditional ceramics (Rincón Romero *et al.*, 2016; it should be noted that a water absorption above 2% corresponds to products with limited frost resistance, not adequate for many architectonic applications, as reported by Kumar *et al.*, 2001).

Layered glass-ceramics offer an interesting solution for the drawbacks of direct sintering. A single-step treatment causes the simultaneous direct sintering of a base body, formed by a glass/waste mixture, and sinter-crystallization of a glaze; the glaze may derive by itself from glass powders obtained by the vitrification of the same starting glass/waste mixture, added with some additives (e.g., zircon, to achieve a light coloration) (Binhussain *et al.*, 2014; Cetin *et al.*, 2015). The poor properties of the base body are no longer significant, since mechanical strength, color and stabilization of pollutants depend on the much denser glazed side (that to be exposed to the environment), showing negligible water absorption. Strength, color and shrinkage of the glaze can be tuned according to the amount and nature of additives. Vitrification of waste becomes more sustainable, since it is applied only to a limited amount of starting materials, to be exploited for the glaze; the single firing reduces the costs of the deposition of a glaze on a previously sintered base body.

The direct sintering of waste glass/inorganic waste is the reference also for a number of glass-ceramic foams. Inorganic waste partially replace glass powders, to be expanded by the action of foaming additives (such as SiC); reacting with the softened glass, during foaming, they yield a substantial crystallization, in turn enhancing the mechanical properties (Fernandes *et al.*, 2009; Zhu *et al.*, 2016; Zhang *et al.*, 2016; Wang *et al.*, 2018; Xi *et al.*, 2018). Interestingly, some glass-ceramic foams without expensive foaming additives. As an example, iron oxide provided by iron-rich minerals, such as basalt scoria (unemployed volcanic mineral, as shown by Marangoni *et al.*, 2014) and metallurgical slags (e.g., slag from the refining of precious metals, as shown by Ponsot and Bernardo, 2013), contributes both to foaming, by oxygen release, (passing from ferric oxide to ferrous oxide) and to crystallization, by formation of iron-containing silicates.

Direct Sintering of Glass-Ceramics With Engineered Crystal Phases

Besides waste, oxides can be considered pure, or in much simpler mixtures. The reaction between oxides and glasses may be easily controlled, e.g., by controlling the particle size and the processing temperature. Oxides can be considered pure, or in much simpler mixtures (compared to many waste streams). The reaction between oxides and glasses may be easily controlled, e.g., by controlling the particle size and the processing temperature. As an example, Müller *et al.* (2009) showed that no substantial alumina dissolution can be observed, from composites of 75 vol% alkali-free calcium-alumino-borosilicate glass and 25 vol% dispersed alumina particles, sintered, starting from fine powders (5 μm), below 900°C. Above this temperature, wollastonite, due to the crystallization of the glass matrix, declines, whereas calcium alumino-silicate (anorthite) is favored, as a consequence of the dissolution of the secondary oxide phase.

Lee *et al.* (2010) showed the substantial mineralogical equivalence between glass-ceramics from sinter-crystallization of a (relatively B- and Al-rich) alumino-boro-silicate glass and reactive sintering of a (relatively B- and Al-poor) commercial borosilicate glass (Corning 7070) powders added with aluminum borate hydrate ($2\text{Al}_2\text{O}_3 \cdot \text{B}_2\text{O}_3 \cdot 3\text{H}_2\text{O}$). In both cases, the crystal phases consisted of $\text{Al}_4\text{B}_2\text{O}_9$ or $\text{Al}_{18}\text{B}_4\text{O}_{33}$ whiskers, known to greatly enhance the fracture toughness of the glass matrix, by crack deflection. The toughening effect of whiskers, in samples derived from commercial boro-silicate glass, was compromised by the abundant residual porosity; however, the phase evolution testified the occurrence of reaction (the simple dehydration of aluminum borate hydrate would lead simply to $\text{Al}_4\text{B}_2\text{O}_9$).

Glass-oxide interactions give an excellent opportunity even for the manufacturing marble-like glass-ceramics, avoiding the expensive processing of Neoparies[®] and enabling the up-cycling of a specified glass, namely clear LCD glass. The glass can be used in both fine and coarse fractions (<90 μm , >600 μm) (Authors' unpublished results), mixed with $\text{Mg}(\text{OH})_2$ and reactive alumina ($\gamma\text{-Al}_2\text{O}_3$), in form of micro-sized powders (<10 μm) as shown by the scheme in Fig. 3(a). Pressed and fired at 1000–1100°C, the mixture easily yields cordierite-based glass-ceramics, without any melting step. The specific phase ($\text{Mg}_2\text{Al}_4\text{Si}_5\text{O}_{18}$, i.e., $2\text{MgO} \cdot 2\text{Al}_2\text{O}_3 \cdot 5\text{SiO}_2$) derives from the chemical reaction between fine LCD glass and the low cost additives, yielding extra MgO and Al_2O_3 ; coarse LCD glass particles simply “dilute” the crystal phases (see the diffraction patterns in Fig. 3(b)). In particular, the newly developed crystals (besides cordierite, spinel, enstatite and another Mg alumino-silicate phase) are formed mainly from fine

Fig. 3 Obtainment of a cordierite glass-ceramic from glass reactive sintering with selected additives: (a) concept; (b) diffraction patterns and esthetic appearance (compared to that of white marble); (c) detail of amorphous zone surrounded by crystals.

glass powders and concentrate around “islands” of un-reacted glass (Fig. 3(c)). Like in Neoparies[®], the marble-like appearance derives from the different crystallization degree of boundaries (crystals and small unreacted glass areas) and cores (residue of coarse powders, unreacted). The crystallization of cordierite is promising for the high infrared emissivity of the specific phase, to reduce overheating under exposition to sunlight (Xiaofang *et al.*, 2002).

Neoparies[®] inspire also directly-sintered wollastonite glass-ceramics (fired at 850–1000°C), obtained from common soda-lime window glass (< 150 μm) mixed with varying amounts (up to 25 wt%) of powdered “crystallization promoter”, in turn corresponding to the direct sintering (at 1100°C) of kaolin clay, CaCO_3 , BaO and ZnO (Zhang and Liu, 2013). Wollastonite crystallizes by reaction between glass and gehlenite ($\text{Ca}_2\text{Al}_2\text{SiO}_7$), from the crystallization promoter. The inclusion of promoter determines a quite delicate trade-off between densification (an increase of solid inclusions, in softened soda-lime glass, obviously complicates the viscous flow) and reaction (wollastonite increases with increasing content Ca-rich promoter), that may be adjusted operating on firing time and temperature. In optimized conditions (2 h at 850°C, 25% promoter), directly-sintered glass-ceramics exhibit an excellent bending strength (exceeding 100 MPa) combined with very limited open porosity (water absorption far below 0.5%). Similar glass-ceramics may be obtained with window glass mixed with pure gehlenite (Si and Ding, 2018).

Albite ($\text{NaAlSi}_3\text{O}_8$) and diopside ($\text{CaMgSi}_2\text{O}_6$) represent further examples of newly formed crystal phases from ‘extensive reactive sintering’ of common soda-lime glass and crystallization promoters, in the form of mullite/enstatite/quartz or enstatite/cordierite mixtures, in turn deriving from the calcination of kaolin and talc (Zhang *et al.*, 2011). CaO, Na₂O and SiO₂ from soda-lime are reactants for the transformation of enstatite (MgSiO_3), mullite ($3\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$) and cordierite into diopside, albite and diopside/albite mixtures, respectively, as follows:

The reaction paths may change according to the chemistry of the glass; a relatively Mg-rich glass may determine the decomposition of mullite, used as crystallization promoter, into silica, in turn “absorbed” in the formation of diopside, and corundum ($\alpha\text{-Al}_2\text{O}_3$), as separate phase (Si *et al.*, 2016).

Diopside-based glass-ceramics are interesting as basis for further reaction. Feng *et al.* (2015) showed that a glass frit, “normally” leading to sintered $\text{CaMgSi}_2\text{O}_6$ glass-ceramics (Feng *et al.*, 2012), may interact with MgTiO_3 powders (up to 14 wt%) and form a diopside glass-ceramic with Mg_2SiO_4 and CaTiO_3 as additional phases (owing to a $\text{Ca}^{2+}/\text{Mg}^{2+}$ exchange between silicates and titanates), upon sintering at 950°C. The phase assemblage can be tuned according to the amount of MgTiO_3 ; in optimized conditions, the resulting glass-ceramics exhibit a very low dielectric constant combined with high quality factor and nearly zero temperature coefficient of resonant frequency (very low dielectric dissipation), useful for application as substrates in telecommunication and satellite broadcasting industry (for frequencies in the microwave range).

The previously mentioned albite deserves a particular attention. It belongs to the vast family of feldspars, known to feature distinctive “framework” crystal structures (“tecto-silicates”), deriving from those of crystalline silica polymorphs (Höland and Beall, 2012). SiO_4 tetrahedra are replaced by AlO_4 units, with the charge deficiency (Al^{3+} instead of Si^{4+}) compensated by the presence of alkali and alkaline earth ions in the spaces between tetrahedra (empty, in the case of silica), so that feldspars are also known as “stuffed derivatives of silica”. The so-called “feldspathoid” minerals are similar, except for a higher degree of silica substitution (higher Al/Si ratio). While alkaline earth feldspars (e.g., anorthite, $\text{CaAl}_2\text{Si}_2\text{O}_8$) and some feldspathoids (e.g., nepheline, $\text{NaAlSi}_3\text{O}_8$, kalsilite, KAlSi_3O_8 , leucite, KAlSi_2O_6) are key constituents in certain glass-ceramics (Höland and Beall, 2012), alkaline feldspars are less common. Pure minerals exhibit an excellent glass-forming ability but the resulting glasses do not crystallize in practical periods of time (Höland and Beall, 2012).

The sinter-crystallization of fine glass powders (multi-component waste-derived glasses or more stoichiometric glasses) has been proven as a fundamental tool for achieving glass-ceramics with such “unusual” crystal phases, owing to the above-mentioned stimulation of crystallization operated by surfaces (Bernardo *et al.*, 2008). Reactive sintering provides a valid alternative, also starting from exceptionally stable glasses, such as lead-containing glasses from dismantled cathode ray tubes. Lu *et al.* (2018) obtained glass-ceramics featuring orthoclase (potassium-sodium feldspar, $(\text{K},\text{Na})\text{AlSi}_3\text{O}_8$; major crystalline phase in an amount of 42–44 wt%) and lead feldspar ($\text{PbAl}_2\text{Si}_2\text{O}_8$) by sintering, at 1000–1100°C, “funnel” glass (lead-containing glass constituting the part of CRTs hidden inside the old TV sets, as described by Ling and Poon, 2014) combined directly with kaolinite or with a mullite/cristaballite mixture (from calcined kaolinite). The obtained phase assemblage provided a successful immobilization of lead ions (in both lead feldspar and residual glass phase).

Fluorine is a fundamental component in glasses converted into many useful glass-ceramics (Höland and Beall, 2012), i.e., in fluorosilicates and in silico-phosphates, including Kokubo’s wollastonite-fluoroapatite glass-ceramics (Hench and Kokubo, 1998). It is not surprising that oxide additives could be replaced by fluorides, in direct sintering approaches to glass-ceramics, starting from waste glasses. Cuspidine ($\text{Ca}_4\text{Si}_2\text{O}_7\text{F}_2$) as well as fluoramphibole crystals (complex fluoro-silicates crystallizing in form of interlocking needles with huge aspect ratio, leading to high fracture toughness; Höland and Beall, 2012) are easily achieved by sintering soda-lime glass with fluorides (LiF , NaF , MgF_2 , CaF_2 , BaF_2) and/or fluormica (e.g., natural mineral close to the stoichiometry of fluorphlogopite, $\text{KMg}_3\text{AlSi}_3\text{O}_{10}\text{F}_2$), at a temperature of 800–1000°C (Zhang *et al.*, 2006; Zhang and Gao, 2007; Si *et al.*, 2012, 2018). Complex structures, such as those of the fluoramphiboles fluorrichterite ($\text{Na}_2\text{CaMg}_5\text{Si}_8\text{O}_{22}\text{F}_2$) and fluorwinchite ($(\text{Na},\text{K})\text{CaMg}_5\text{Si}_8\text{O}_{22}\text{F}_2$), form by interdiffusion between softened glass and additive (Na^+ and Ca^{2+} from glass to fluormica, K^+ , Mg^{2+} and F from fluormica to glass) (Zhang *et al.*, 2006). It should be noted that mica minerals may have hydroxyls instead of F (e.g., phlogopite is described by the general formula $\text{KMg}_3\text{AlSi}_3\text{O}_{10}(\text{F},\text{OH})_2$), so that glass/mica composites lead to reactions also leading to F -free phases, such as diopside (Faeghi-Nia, 2011).

Reactive sintering implies a “microstructural design”, not only in terms of chemical formulation and mineralogy, but also in terms of “morphology”. Those based on lithium disilicate ($\text{Li}_2\text{Si}_2\text{O}_5$) were the first glass-ceramics developed by Stookey; although “older” than any glass-ceramic system, they are still quite attractive, especially in restorative dentistry, because of their high strength and their translucency, comparable to that of natural teeth (Höland and Beall, 2012). The controlled crystallization of a suitable glass (“LD” glass) yields a multitude of tiny crystals, even below 1 μm (Zhao *et al.*, 2014). Some crack deflection at glass/crystal interface is observed (the fracture toughness may exceed 3 $\text{MPa m}^{0.5}$; Höland and Beall, 2012), but at a lower level, compared to the cases of ceramics with highly elongated interconnected crystals (such as Si_3N_4 and SiAlON ceramics or the previously mentioned fluoramphibole glass-ceramics). Zhao *et al.* (2014) succeeded in developing glass-ceramics with highly elongated $\text{Li}_2\text{Si}_2\text{O}_5$ crystals by reactive sintering under pressure (at 820–890°C) of silica glass and lithium metasilicate (Li_2SiO_3), previously obtained from the crystallization (at 490°C) of a stoichiometric glass (50 mol% Li_2O , 50% SiO_2 ; “LM” glass), according to:

Ideally, the reaction reproduces what typically found, on a finer scale, in conventional lithium disilicate glass-ceramics, i.e., the formation of the desired phase after the precipitation of lithium metasilicate precursor (Höland and Beall, 2012). In practice, the

reaction is conducted with some silica excess (resulting in some residual glass phase) and in the presence of some LD glass powders: large grains, from the reaction, may coexist with small ones from the crystallization of LD (Zhao *et al.*, 2014). The optimization of the microstructure, according to the relative amounts of components and the sintering conditions is the object of current research (Zhao, *et al.*, 2019).

Glass-Ceramics From the Interaction Between Glass and Reactive Binders

The quality of the previously mentioned glass-ceramic sealants for SOFC/SOEC is strongly conditioned by the debinding step. Usual manufacturing implies manual deposition or screen-printing of fine glass powders mixed with organic binders, e.g., PVB (Sabato *et al.*, 2016), dispersed in a solvent. The burn-out of organic matter must be completed at the early stages of heat treatment, to avoid the development of cracks and pores, like in any other ceramic systems (Cima *et al.*, 1989; Evans *et al.*, 1991; Chartier *et al.*, 1995; Enneti *et al.*, 2012). In the case of SOFC/SOEC, however, the debinding involves sandwich structures, with glass powders laying between a metal substrate and a ceramic electrolyte. The sandwich is mechanically consistent before debinding and after sintering (with concurrent crystallization); nothing can be said in the intermediate stage, with glass powders slightly bound just by mutual attrition. There is a substantial risk of misalignment of the pieces to be sealed.

Recent investigations have highlighted the potential of alternative binders, consisting of silicone resins, i.e. materials belonging to the vast class of “preceramic polymers”, for the distinctive ability to leave an abundant ceramic residue, when subjected to heat treatments above 500°C (Colombo *et al.*, 2010; Bernardo *et al.*, 2014). If treated in air, silicones transform into highly reactive amorphous silica, that may dissolve in the pyroplastic mass determined by the viscous flow of a glass filler. This opportunity was first shown by Ohl *et al.* (2011), who developed translucent glass scaffolds starting from a silicone resin filled with Duran® glass powders.

The use of a silica-yielding binder involves a revision of the formulations, since the chemistry of the glass filler evidently changes, especially operating with silicones with high ceramic yield (the amount of silica may exceed 80% of the weight of the silicone polymer, as reported by Colombo *et al.*, 2010). The revision may be applied to the overall formulation, operating with extra fillers, or to the chemistry of the glass. Ohl *et al.* (2011) compensated the extra silica left from the silicone by adding Na₂O and B₂O₃, by means of a secondary filler (borax), so that the overall chemical formulation of Duran glass could be preserved. In other cases, the “polymer-derived” silica was exploited to form extra crystal phases, reacting with selected fillers, beside those formed by crystallization of the starting glass, e.g., normally yielding a wollastonite-apatite glass-ceramic (Elsayed *et al.*, 2015; Zocca *et al.*, 2015). The overall chemistry changes, but the approach is undoubtedly flexible.

The revision of the formulation of the starting glass offers a simplification, in the sense that the final product is determined just by chemical interaction of silicone binder and glass, with no other additive. Starting from a reference glass-ceramic system (sinter-crystallized, from powder bound by conventional fugitive binders, as reported by Elsayed *et al.*, 2018b), the parent glass is replaced by a “silica-defective variant”, for which the batch comprises a reduced amount of silica-yielding raw materials. Once finely powdered, the silica-defective glass is embedded in a silicone binder, degrading into reactive silica upon heating; the mixing of softened silica-defective glass and silica residue of the binder yields a mixture with the same overall oxide formulation of the reference glass. For a proper formulation (i.e., amount of SiO₂ “removed” from the reference glass, to form the silica-defective variant, and “recovered” by means of the binder), the mixture undergoes crystallization, leading to a glass-ceramic with a nearly identical phase assemblage than the original glass-ceramic, and with limited residual porosity as illustrated by the scheme in Fig. 4. The approach has been just applied to SOFC/SOEC sealants and scaffolds from direct ink writing of silicone-glass pastes (Elsayed *et al.*, 2019b); the effectiveness of mixing should be assessed for many other glass-ceramic systems, but a large potential is envisaged even for other applications, e.g., glass-ceramic coatings (Parchovianský *et al.*, 2016).

The investigations on scaffolds for bone tissue engineering actually highlighted a specific advantage of silicones as reactive binders (Elsayed *et al.*, 2019a). A reference glass CaO-Na₂O-B₂O₃-SiO₂ system (Fernandes *et al.*, 2016) was used to form reticulated scaffolds, by direct ink writing of glass powder and fugitive binder, which exhibited a substantial viscous collapse upon ceramization. The viscous flow could be limited by forcing the crystallization, by rapid heating, but this could modify the phase assemblage as well. On the contrary, powders of a silica-defective variant underwent softening, but remained supported by the stiff “silica skeleton” from the silicone; the desired phase assemblage was achieved without substantial viscous collapse of the reticulated scaffolds. The supporting role of reactive silicone binders in glass-ceramic components processed by means of additive manufacturing technologies finds analogies in other ceramic systems, e.g., in TiO₂ porous structures from powder-bed 3D printing of titania powders bound by Ti-based organometallic compounds (Grant *et al.*, 2018).

Besides in the chemistry, silicones are attractive also for “basic” operations, in powder-based 3D printing. As shown by Zocca *et al.* (2015), silicone powders may be just “physically” mixed with glass powders and transformed into a “glue” for the same glass powders, by a simple solvent jet. In other words, solvent droplets “activate” the binder, by partial dissolution; this avoids any risk of injectors clogging or inhomogeneous deposition, by progressive evaporation of solvent, when depositing solvent-binder mixtures.

The use of silicone reactive binders actually brings also advantages in the introduction of extra phases. More precisely, silicone/glass mixtures offer a simple opportunity for the development of composites involving silicates combined with a carbon phase, which represent a very promising class of biomaterials (Thamaraiselvi and Rajeswari, 2004). Besides mechanical properties, the

Fig. 4 Schemes for the obtainment of glass-ceramics and glass-ceramic matrix composites from “silica-defective glasses” and reactive silicone binders.

carbon phase can improve the functionalities, e.g., by enabling photothermal effect (in turn exploited for ablation therapy of cancer cells, as shown by [Chen et al. \(2015\)](#)). If the firing is not performed in oxidative atmosphere, silicones yield a silicon oxycarbide (SiOC) ceramic residue, which can be roughly described as a silica rich phase (featuring some Si–C bonds, besides Si–O) mixed with carbon nanosheets, at least below 1200°C (phase separation with formation of SiC crystals is known to occur at higher temperatures, as reported by [Colombo et al., 2010](#)). The silica-rich phase may be used to react with a silica-defective glass, whereas the carbon phase could stay inert, as shown by [Fig. 4](#) (bottom part).

[Fig. 5](#) shows a scaffold (Authors’ unpublished results) from direct ink writing of a silica-defective glass (based on a glass yielding wollastonite-diopside glass-ceramics ([Fiocco et al., 2015a](#)), with SiO_2 reduced by 15 wt%), fired at 900°C in flowing N_2 . The glass was mixed with MK polymer (90 wt% of the silica to be recovered, Wacker Chemie, Germany) and fumed silica (10 wt% of the silica to be recovered); the mixture was designed in order to exploit just the silica-rich phase of SiOC. [Fig. 5](#) provides also an interesting comparison of the diffraction patterns of composites with those of mixtures, calculated in order to be fired in air, with all MK transformed into silica (mixtures with glass A, with 7.5% SiO_2 recovered from silicone and fumed silica, and with glass B, with 15% SiO_2 recovered from silicone and fumed silica). It can be clearly seen that the patterns do not substantially differ from

Fig. 5 Obtainment of glass-ceramic scaffolds from silicone polymer and “silica-defective” glasses, in both air and nitrogen.

each other or from that of a glass-ceramic from the reference glass. An exception is given by the intensity of crystal peaks, known to be proportional to the amounts of crystal phases: the intensity of peaks of silicate phases in the composite was downscaled, with a good matching with the expected “dilution” operated by the extra (amorphous) carbon phase.

Polymer-Derived Glass-Ceramics

The previously mentioned investigations all actually configure examples of a “high glass approach”. Glass powders, however, may be used even in low amounts (‘low glass approach’), to support silicone-derived glass-ceramics (Fiocco *et al.*, 2015a). In fact, an ultimate example of glass-ceramics by direct sintering may be represented by silicones interacting with oxide fillers (carbonates, sulfates, hydroxides or directly oxides), in the form of both micro- and nano-sized powders. The quasi-molecular mixing between silica from the polymers and other oxides generally favors the obtainment of highly phase pure silicate ceramics, at low temperatures. These ceramics may be seen as a subgroup of the so-called “polymer-derived ceramics” (ceramics from the transformation of preceramic polymers, Colombo *et al.*, 2010), mixed with “passive” (not reacting with the ceramic residue of the preceramic polymer) or “active” (reacting with the residue and/or with firing atmosphere) fillers, as proposed by Greil (1995), (1998), but they have specific features.

The distinctive, partially covalent chemical bonding of silicates complicates the ionic interdiffusion, especially in the case of quite complex structures, such as mixed silicates, e.g., Ca-Mg, Ca-Zn silicates (Bernardo *et al.*, 2014). The desired phases (i.e. those predicted according to the molar balance between silica and other oxides) are easily developed once secondary fillers (Na-phosphate, Na- and Ca-borates) do not contribute to (or only to) the crystal phases but yield some liquid phase upon firing. The ceramic residue of silicones is amorphous and highly defective (Bernardo *et al.*, 2014) but, as mentioned before, “solid”

(silicates are formed well below the transition temperature of silica glass); the extra liquid dissolves the other components and enables a faster ionic interdiffusion, and finally forms a boro- or phospho-silicate glass, in low amounts (Fiocco *et al.*, 2015a,b).

Borates and phosphates are actually “multifunctional” fillers, since they may:

- (1) Bring components for the synthesis of the desired phase (like the other fillers);
- (2) Release water vapor (when used in their hydrated form), at relatively low temperature, i.e., in silicones still in their polymeric state (enabling a significant foaming);
- (3) Bring components for the formation of a liquid phase, later transforming into a glass, also by partial dissolution of the other components.

Polymer-derived ceramics may turn into “polymer-derived glass-ceramics”. Pre-ceramic polymers are confirmed in their role of transferring polymer forming technologies (injection, extrusion, foaming, etc.) to the domain of ceramics.

In the last systems, glass powders may be used as extra fillers. If featuring the same stoichiometry of the silicone-filler mixture, they lead to glass-ceramics with nearly identical phase assemblage, independently from their content. In the most interesting cases the amount of glass is limited (not exceeding 30 wt%), and it is intended to correct a fundamental issue of “polymer-derived glass-ceramics”, represented by the formation of cracks, in turn due to gas release (from ceramic transformation of silicones), still in progress at the moment of the formation of (rigid) crystals. An increased amount of borates or phosphates would lead to enhanced viscous phase, enabling some stress relaxation, with risks of significant deviation from the stoichiometry of the reference silicates; operating with glass, the viscous phase is enhanced as well, but the crystallization of the same glass keeps the crystallization degree substantially unchanged (Fiocco *et al.*, 2015b).

Also in the case of “polymer-derived glass-ceramics” one fundamental application concerns additive manufacturing of bio-ceramic scaffolds, namely by direct ink writing of silicone-based pastes, including glass powders or not. Recent experiences showed the manufacturing of Biosilicate[®] glass-ceramic scaffolds just from oxide fillers (comprising phosphates) (Elsayed *et al.*, 2019c); on the contrary, stronger wollastonite-diopside scaffolds were achieved by using a paste comprising a glass with the same overall formulation of the silicone-filler mixture (SiO₂: 51.7 wt%; CaO: 32.1%; MgO: 11.5%; Na₂O: 2.2%; P₂O₅: 2.5%) (Elsayed *et al.*, 2017b).

Glass Reaction Sintering as a New Route to Glass-Making

Preparing a glass by sintering rather than melting allows the reduction of technological temperatures and the formation of complex shapes by the methods of ceramic technology. The practical melting temperature of a glass is significantly higher than the thermodynamic melting point (the liquidus temperature) of a crystal mixture of the same composition, because high viscosity at the liquidus temperature slows the dissolution of particles and arrests glass refining. Sintering of pulverized glass or glass microbeads provides a possible alternative for glasses with particularly high processing temperatures (e.g., alumina-based glasses) (Wang *et al.*, 2001; Rozenflanz *et al.*, 2004).

Sintering may lead to glass and glass-ceramic bulk samples even without any preliminary preparation of glass particles. Reaction sintering under isostatic pressure (RSIP) offers interesting opportunities: the formation of small amounts of a low viscosity liquid intermediate phase, by direct reaction between some reactants (e.g., Na₂O and SiO₂), triggers the dissolution of the other components, enabling the obtainment of near net-shape glass bodies at much lower temperatures than melting. This is particularly important when the corrosion of melter components and the volatility of glass constituents are of concern, like in the stabilization of refractory-rich high level radioactive waste (Lutze *et al.*, 1998; Gong *et al.*, 1999, 2000). The possible separation of ZrO₂ particles is interpreted as a result of super-saturation of the glass phase rather than incomplete dissolution (Gong and Lutze, 2002).

Besides radioactive waste, the approach can be extended to the manufacturing porous bioactive ceramics (with pores 100–200 μm and ≤5 μm in diameter) (Gong *et al.*, 2001), in pellets pressed at 7 MPa and simultaneously heated at 950°C (at least 250°C below the temperature that required by glass melting). Amorphous silica, P₂O₅, Ca(OH)₂ and Na₂C₂O₄ (sodium oxalate) lead to completely amorphous pieces, while the addition of hydroxyapatite yields a rhenanite (β-NaCaPO₄)/wollastonite glass-ceramic, according to specific reaction path:

- (1) Formation of rhenanite (with water vapor release, leading to pores) by reaction between apatite and sodium silicate phase, accompanied by diffusion of calcium in sodium silicate phase:

- (2) Crystallization of wollastonite from calcium-enriched sodium silicate phase:

Like in the case of the above-mentioned polymer-derived glass-ceramics, there is potential for a real design of the crystal phases.

Concluding Remarks

Glass reactive sintering may be seen as a vast domain of technologies, relying on extensive reactions between glass particles and (possibly) selected additives. The control of reactions is not significant just for the microstructural development, including the formation of “unusual” phases (e.g., feldspar phases, free carbon) but also for the overall processing, including the most recent trends, such as additive manufacturing. The huge number of combinations between glass powders, oxide additives, reactive binders etc. opens the way for a new generation of glass-based products, in key areas of industrial development (health, energy, environment), to be disclosed in the near future.

Acknowledgments

This paper is a part of dissemination activities of the project FunGlass (Center for Functional and Surface Functionalized Glass). This project has received funding from the European Union’s Horizon 2020 research and innovation program under grant agreement No 739566 [J. Kraxner]. The authors gratefully acknowledge also the support of the European Community’s Horizon 2020 Program through a Marie Skłodowska-Curie Innovative Training Network (“CoACH-ETN”, g.a. no. 642557) [A. Rincon, E. Bernardo] and of Nippon Electric Glass Ltd [E. Bernardo], for additional funding and for supplying LCD glass.

Glasses and Glass-Ceramics as Sealing Materials

María J Pascual, Ceramics and Glass Institute (CSIC), Madrid, Spain

Introduction

Sealing glasses have traditionally been used for the sealing of lamps and vacuum tubes by means of a slow and expensive process which required sealing temperatures close to 1400°C. The beginning of the development of sealing glasses started with research carried out by Owens Illinois and Corning Glass Works. The objective was the preparation of glasses with good flow properties at temperatures around 500°C and with a thermal expansion coefficient sufficiently low to be applied in sealing the front plate of TV tubes. Glasses in the system ZnO-PbO-B₂O₃ were developed for this purpose (Sinhdeo and Shukla, 1984).

At the end of the 1950's, a research group from Fairchild Semiconductor Company considered that the sealing glasses developed by the television industry could also be used to join the alumina plates employed to encapsulate the silicon integrated circuits and protect them from environmental humidity. Nevertheless, the thermal expansion coefficient of the glasses in the system ZnO-PbO-B₂O₃ ($7\text{--}12 \times 10^{-6}\text{K}^{-1}$) is too high to adjust to an alumina-based ceramic ($\sim 6.5 \times 10^{-6}\text{K}^{-1}$) and to the metallic conductors embedded through the glass ($4\text{--}4.7 \times 10^{-6}\text{K}^{-1}$). The modifications introduced in the glass composition in order to decrease the thermal expansion coefficient would invariably lead to an increase in the softening temperature. The solution to the problem consisted of uniformly dispersing a ceramic phase of very low thermal expansion coefficient; these composite materials provided a sufficiently wide thermal expansion coefficient interval able to cover the needs of the microelectronics industry throughout the 1960s.

The increasing complexity of the silicon integrated systems demanded new sealing glasses with sealing temperatures as low as (<450°C) which led to the development of glasses with high thermal expansion coefficients and very low softening temperatures and also to the study of glass-ceramics for sealing (Forbes, 1967; Ray *et al.*, 1973a,b, 1976; Tindyal and Ott, 1978). These latter materials combine the good thermal properties of the glasses with a high mechanical and chemical resistance.

In parallel to the advances in the preparation of new glass compositions for sealing, much effort has been dedicated to the development of new sealing procedures and with the purpose of understanding the reaction mechanisms taking place at the glass/ceramic and glass/metal interfaces. The extensive literature on these topics, more than 3500 citations (source: Scopus), is indicative of the complexity and technological and scientific importance of sealing glasses and glass-ceramics.

Requirements for Sealing Glasses

The glass properties must be precisely adjusted to certain values in order to be used as a hermetic seal in a particular system. The specifications that the glass must fulfill in order to be effective as a sealing material depend on the nature of the materials to be sealed, the complexity of the system, the different functionalities that the seal must perform and the system working conditions (Sinhdeo and Shukla, 1984). In many of the applications, the glass sealant will not only carry out the sealing function but also perform other functions such as electrical insulator, environmental protection, chemical and mechanical protection, diffusional barrier, etc.

Flow Temperature and Viscosity

The glass fluidity required to perform the seal depends on the adjustment between the parts to be sealed, the application of the sealing glass and the sealing time. Using polished surfaces and under pressure, sealants with viscosities as high as 10^{10} dPa s or even higher may be employed. Nevertheless, when there is a poor adjustment between components, considerable fluidity is necessary; the viscosity must be as low as 10^4 dPa s or even lower. In any case, the sealing must be carried out at a temperature below the melting temperature or the degradation temperature of the materials to be sealed. Normally, the melting temperature of the materials to be sealed is sufficiently high and the limitations come from the maximum temperature at which the whole system can be exposed without suffering damage. This is the case for electronic systems where the complexity and sensitivity of the integrated circuits impose sealing temperatures even lower than 200°C. This requirement considerably limits the possible suitable compositions.

When a glass-ceramic is applied, there is an increase of viscosity due to the crystallization process with the corresponding adjustment of properties and a final rigid material at high temperature can be obtained, desirable for the most refractory sealing applications. Fig. 1 shows the viscosity-temperature curves for some sealing glasses for solid oxide fuel cells (SOFC) with typical sealing and operation temperatures between 800 and 950°C (Rodríguez-López *et al.*, 2020). After crystallization these glasses become rigid seals with final viscosities at the operation temperature around 10^{12} dPa s which make them mechanically stable.

Together with direct glass viscosity measurements using a high temperature viscometer, hot-stage microscopy is a very useful tool to investigate the sintering and flow of glass powders, providing information about the relevant viscosity points, wettability and adherence on different substrates (Pascual *et al.*, 2005; Lara *et al.*, 2004).

Fig. 1 (A) Viscosity-temperature curves for the sealing glasses 7.5B(Ba) and 10B(Sr) for SOFC. Fit of the experimental points: VFT equation (continuous lines) and MYEGA equation (dotted lines). (B) Viscosity curves vs. T_g/T for the glasses 7.5B(Ba), 10B(Sr), window glass and silica, the continuous lines show the fit with MYEGA equation. After Rodríguez-López, S., Malzbender, J., Justo, V.M., *et al.*, 2020. Thermo-mechanical stability and gas-tightness of glass-ceramics joints for SOFC in the system MgO-BaO/SrO-B₂O₃-SiO₂. *Frontiers in Materials* 7. doi:10.3389/fmats.2020.00019.

Thermal Expansion Coefficient

The thermal expansion coefficient (α) must be adjusted to one of the materials to be sealed from room temperature up to the glass transformation temperature. The differences in thermal expansion between the glass and the materials to be sealed can generate mechanical stresses provoking fracture of the glass or the loss of adherence between the glass and the system materials (Varshneya and Mauro, 2019; Dai *et al.*, 2017). The fit of α will, therefore, influence the mechanical stability of the system, especially in those cases in which it is going to be under thermal cycles of heating and cooling during its useful life (Rodríguez-López *et al.*, 2017). As a reference, stresses generated due to thermal expansion coefficient differences equal to or lower than $0.5 \times 10^{-6} \text{K}^{-1}$ are considered tolerable. In some cases, a suitable design of the seal geometry can determine that the generated mechanical stresses are compressive, reinforcing the mechanical properties of the system.

The α of glass materials with fixed composition, structure and microstructure is time independent. When the material constituting the seal is a glass-ceramic, it is necessary to consider the dimensional as well as thermal expansion coefficient changes that will occur during the glass devitrification process, specially taking into account that, in most cases, the sealing, nucleation and crystal growth take place during a unique and continuous process. Fig. 2 shows an example of a good fit of the thermal expansion between glass-ceramics and steels, FeCrAlloy and Crofer22APU. The glass-ceramics were obtained from different thermal treatments of the glass Mg1.5–55. The crystallization process ensures a better fit of the α due to the crystallization of phases with the desired α (Lara, 2006).

Adherence

The establishment of a hermetic seal implies the formation of an interface between the glass material and a ceramic or metallic material. The joining at the interface can take place as a consequence of van der Waals forces or by means of the formation of chemical bonding through different mechanisms that comprise interdiffusion, oxidation and phase transformations.

The thermomechanical stability of the interface requires the establishment of a chemical equilibrium. The glass/metal and ceramic/metal interfaces are not normally compatible from the point of view of the redox reactions, and the reactions taking place imply metal oxidation and the reduction of a cation for the glass or ceramic material. In industrial processes, the necessary oxide layer for the equilibrium at the interface is generated by means of the pre-oxidation of the metallic materials (Shen *et al.*, 2019; Fakouri Hasanabadi *et al.*, 2020).

Chemical Durability

In many applications, the sealing glass performs a protection function against attack from ambient humidity or very corrosive atmospheres. The technical problem in many cases is to make the sealing temperature low enough to carry out the sealing without

Fig. 2 Dilatometric curve of Mg1.5-55 glass and corresponding glass-ceramics obtained after treatment at 850°C during different times (from 1 h to 1000 h) and the dilatometric curve for steels FeCrAlloy and Crofer22APU. After Lara, C., 2006. Sellos vitrocerámicos del sistema RO-BaO-SiO₂ R=Mg, Zn para pilas de combustible de óxido sólido SOFC. Ph.D. thesis. Universidad Autónoma de Madrid (UAM).

damaging the system, and with a high chemical resistance. In conventional glasses, these properties vary in opposing senses with the composition.

New applications demand sealing glasses with, for example, a high resistance against attack from molten salts or dual atmospheres (reducing/oxidizing) at a high temperature, high enough to achieve gas-tightness and avoid diffusion problems that limit the development of certain energy-generation systems (Pascual *et al.*, 2003; Rodríguez-López *et al.*, 2016b).

Electrical Resistance

Glass is often going to be the insulating material between two metallic conductors. In addition, to the previously mentioned specifications, it is necessary to add a high electrical resistance that ensures suitable electrical insulation between conductors (Rodríguez-López *et al.*, 2016b). In many cases, alkaline-free glasses are prepared which have a high electrical resistance, albeit at the expense of increasing the glass softening temperature.

Control of Emission Gases

The sealing glasses must not generate, either during the sealing process or operation, reaction products which could damage the system to be sealed. The emission of traces of water vapor can particularly affect systems sensitive to humidity, such as integrated systems.

The outlined specifications constitute those that the sealing material must generally fulfill. The importance of any of them will depend on the specific application. Due to the high number of specifications, often required simultaneously, the formulation of sealing glasses and their treatment have become a field of research and development of high technological impact.

Compositions of Glasses for Sealing

Sealing and enameling glasses are classified according to some of their characteristics such as composition, thermal expansion coefficient, dilatometric softening temperature or the specific application in which they are used (Donald, 1993a; James, 1995; Takamori, 1979). On the other hand, the final seals can be classified in different categories according to different criteria. As a consequence, the seals can be classified as a function of geometry, type of metal or alloy used for the metallic parts, preparation method, adherence mechanism or nature and intensity of the residual mechanical stress of the seal.

Frequently, the sealing glasses are classified into two wide categories according to the α value. Hard glasses are those with α lower than $5 \times 10^{-6} \text{K}^{-1}$ and for soft glasses, α is higher than $8 \times 10^{-6} \text{K}^{-1}$. In general, the glasses with high α have relatively low transformation and softening temperatures and are often referred to as sealing glasses. On the contrary, low α glasses have high transformation and softening temperatures.

Table 1 Compositions of silicate and borosilicate glasses for sealing (mol%)

SILICATE GLASSES												T_s ($^{\circ}\text{C}$)	$\alpha \cdot 10^6 \text{K}^{-1}$

Due to the relationship of the nature of the oxide glass formers and the final properties, it is scientifically very appropriate to classify the sealing glasses according to the glass forming system they belong to. In this case, two large groups can again be distinguished, namely glass and glass-ceramic materials.

Glass Materials for Sealing

Silicate and borosilicate glasses

Many glass compositions for sealing are based on silicate and borosilicate systems (Kreidl, 1983). The most common systems include alkaline silicates and borosilicates, lead silicates, zinc and lead silicates, lead borosilicates and zinc borosilicates (Table 1). Lithium oxide is a constituent in many compositions, particularly mixed alkali compositions. Alumina is a constituent of almost all compositions due to its stabilizing effect.

The α and softening temperatures of these glasses cover a wide range of values, between 2.3 and $15 \times 10^{-6} \text{K}^{-1}$, and between 400 and 850°C , respectively. Table 1 lists some typical compositions and thermal properties of the corresponding glasses (Pascual *et al.*, 1997).

Borate glasses

Many of the glass-forming systems include boron oxide as a main constituent, together with alumina, lead and zinc oxides.

Most of these glasses possess softening temperatures lower than 500°C , and are the basis of the low temperature sealing glasses with wide application in microelectronics (Donald, 1993a). Their range of α , $(5 - 15) \times 10^{-6} \text{K}^{-1}$, makes them compatible with materials such as alumina, metallic alloys and steels. The addition of metallic halides provides glasses with very low softening temperatures, high α and low viscosity. However, lead oxide or lead fluoride is avoided in sealing-glass compositions due to their toxic character. The chemical durability of the borate glasses, although higher than that of phosphate glasses, is lower than that of silicate and borosilicate glasses.

Phosphate glasses

Phosphate glasses for sealing contain phosphorus proportions around 50 mol% due to the higher stability of this type of composition against hydrolytic attack (Ray *et al.*, 1973a,b, 1976; Tindiyala and Ott, 1978; Kobayashi, 1987; Chambers *et al.*, 1989; Abe and Hosono, 1989; Peng and Day, 1991a,b). As a consequence of the particular structure of these glasses, the attack by water occurs through a mechanism of hydrolysis of the phosphate chains and congruent glass dissolution (Martin, 1991; Bunker *et al.*, 1984; Rajaram and Day, 1988). The low resistance against hydrolytic attack has limited the commercial application of many of these glasses and has hindered taking advantage of their good thermal and optical properties. The phosphate glasses exhibit high α together with very low softening and melting temperatures, both very relevant properties from the point of view of low temperature sealing.

Resistance to hydrolytic attack may be improved by adding alkaline-earth oxides or high polarizability metals, capable of creating chelates with non-bridging oxygens of the phosphate chains, and thereby increasing their interconnection (Ray *et al.*, 1973a,b, 1976; Tindiyala and Ott, 1978). Incorporation of alumina, even in small amounts, considerably improves the chemical resistance of the phosphate glasses due to the capability of aluminum for establishing bridging oxygens between different phosphate chains. Unfortunately, the improvement in the hydrolytic resistance of the phosphate glasses produced by the addition

Table 2 Some commercial sealing glasses

Manufacturer and code	Type of glass	Application	T_s (°C)	Operating T (°C)	$\alpha \cdot 10^6 K^{-1}$
Corning 1990	Alkaline phosphate	Seal for iron	500	512	$\alpha_{0-300} = 12.4$
Schott 8095	Alkaline lead silicate	Seal for copper	630	982	$\alpha_{20-300} = 9.1$
Schott 8512	Glass containing FeO	Seal for 52Ni/Fe alloy	660	975	$\alpha_{20-300} = 9.1$
Schott 8418	Alkaline alkaline-earth silicate	Seal for alloy 51Ni/1Cr/Fe	708	1.035	$\alpha_{20-300} = 9.0$
Schott 8531	Lead silicate	Seal for copper/Semiconductor encapsulation	585	822	$\alpha_{20-300} = 9.0$
GB Glass GS85	Alkaline alkaline-earth borosilicate	Graduated seals	710	–	$\alpha_{50-400} = 8.3$
Schott 8454	Alkaline alkaline-earth silicate	Seal for alloy 28Ni/23Co/Fe and alumina ceramics	745	1.050	$\alpha_{20-300} = 6.4$
Corning 7056	Borosilicate	Seal for Kovar	718	1.058	$\alpha_{0-300} = 5.2$
Schott 8250	High boron contain glass	Seal for Mo and alloy 28Ni/18Co/Fe	715	1.060	$\alpha_{20-300} = 5.0$
Corning 7052	Borosilicate	Seal for Kovar, Mo or W	712	1.128	$\alpha_{0-300} = 4.6$
Corning 7720	Borosilicate	Seal for W	755	1.146	$\alpha_{0-300} = 3.6$
Schott 8435	Borosilicate	Seal for Kovar or Mo and Al_2O_3	550	800–900	$\alpha = 5.8$

of stabilizing oxides provokes a parallel increase in the softening temperature and a decrease in α . Some of the compositions of phosphate sealing glasses can be found in refs. (Brow *et al.*, 1998; Brow, 2000; Morena, 2000).

An alternative method to improve the hydrolytic resistance without substantially altering the thermal properties is nitridation in an anhydrous NH_3 atmosphere. Nitrogen incorporation up to proportions of 15 wt% produce an increment of the hydrolytic resistance of up to three orders of magnitude without notably diminishing the α value (Pascual and Durán, 1996a,b). Compositions of nitrided phosphate glasses belong to the alkaline metaphosphate, alkaline-earth metaphosphate, and alkaline-alkaline earth phosphate and lead alkaline phosphate systems. Nitrogen incorporation in the phosphate glasses provides sealing glasses with a wide range of thermal expansion coefficients and very low sealing temperatures. The hydrolytic resistance of these glasses with maximum nitrogen content is of the same order of magnitude as those of commercial soda-lime glasses.

Recently, the addition of a certain proportion of silicon nitride has been proposed to tailor the structural, chemical and thermal properties of phosphate sealing glasses (Jiang *et al.*, 2018).

Glasses based on other oxide glass formers

A certain number of sealing glass compositions are based on less common oxide formers, in particular, Sb_2O_3 , As_2O_3 and V_2O_5 (Zhang *et al.*, 2014). Some of the compositions containing Sb_2O_3 present high α , $\alpha > 20 \times 10^{-6} K^{-1}$, together with a very low softening temperature, $< 300^\circ C$.

Devitrifying Sealing Glasses

The glasses described in the previous sections remain in the glassy state during and after sealing. Nevertheless, sealing glasses which totally or partially crystallize during the sealing process have been developed (Lee *et al.*, 1990; Volf, 1984). These glasses, firstly described by Claypoole (1959), are called devitrifying sealing glasses. They were originally based on zinc and lead borate systems of high thermal expansion coefficient or on zinc borosilicate systems of lower thermal expansion coefficient (McMillan, 1979). The crystallizing sealing glasses are normally used as glass powder mixed with an agglomerant; crystallization takes place during sealing through a mechanism of superficial nucleation.

In Table 2, some commercial glasses based on some of the previously mentioned systems are listed. There is a great variety of commercial glasses developed for sealing numerous metals, alloys and semiconductors, including silicon, tungsten, molybdenum, platinum and low expansion nickel-iron alloys containing 42%, 46% and 52% of Ni, stainless steels and iron.

Glass-ceramic materials for sealing

Glass-ceramic materials, defined as ceramic polycrystalline materials, prepared by controlled crystallization were developed for the first time by Corning Glass Works in the 1950's (Strand, 1986; Grossman, 1982; Beall and Duke, 1983; Smith, 1989; Donald and Cahn, 1993b; Deubener *et al.*, 2018). Nowadays, glass-ceramic materials are becoming more relevant in the field of glass/metal sealing. These materials are processed and formed in the same way as glass followed by a controlled crystallization process through a thermal treatment. The crystallinity of the sealing glass-ceramics can exceed 90%, while the size of the crystals is not normally greater than $1 \mu m$. The crystalline phases present, their proportion and microstructure depend on the glass composition, the thermal treatment and the presence or absence of nucleating agents and their nature.

The principles for the design and fabrication of glass-ceramic sealants are very similar to the fabrication of glass/metal seals. Nevertheless, the properties can be varied in a wide range of values through careful control of the crystallization process.

In conventional glasses, crystallization initiates at the surface and progresses towards the interior of the material giving rise to microstructures with large anisotropic crystals. These materials are in general mechanically weak because the big crystals act as

Fig. 3 Thermal cycle scheme for the fabrication of a seal with glass-ceramic S. (a) with Inconel 718 and Hastelloy C276, (b) with stainless Steel 430 type. After Pascual, M.J., Pascual, L., Durán, A., 1997. Vidrios y vitrocerámicos para soldadura: usos tradicionales y nuevas áreas de aplicación. Boletín de la Sociedad Española de Cerámica y Vidrio 36 (4), 383–398.

stress concentration centers. The control of the crystallization process through the introduction in the composition of suitable proportions of nucleating agents and a careful thermal treatment can, on the other hand, lead to the formation of isotropic microstructures composed of small randomly oriented crystals, linked by a residual glassy phase.

A glass-ceramic material is normally prepared employing a two-step thermal treatment (Fig. 3). During the nucleation step, a great number of small heterogeneities or crystallization nuclei are formed in the glass bulk from which crystals are developed in a second thermal treatment step at a higher temperature than for nucleation.

In practice, high nucleation rates are achieved by adding suitable nucleating agents to the batch. The most employed nucleating agents include elemental metals, oxides, metallic halides and sulfides (McMillan *et al.*, 1966a; Grossman, 1982). The mechanism according to which a nucleating agent acts has not clearly been determined for all glass-ceramic systems. Nevertheless, some mechanisms have been proposed (McMillan *et al.*, 1966a) which imply the precipitation of small crystals of a compound formed by the reaction between the nucleating agent and the glass constituents.

In a first approximation, the thermal expansion coefficient of a glass-ceramic material is an additive function of the thermal expansion of the different phases present and may be represented by the following relationship (Hammeter and Loehman, 1987):

$$\alpha_{\text{glass-ceramic}} = \frac{\left(\frac{\alpha_1 K_1 W_1}{\rho_1} + \frac{\alpha_2 K_2 W_2}{\rho_2} + \dots \right)}{\left(\frac{K_1 W_1}{\rho_1} + \frac{K_2 W_2}{\rho_2} + \dots \right)} \quad (1)$$

where α_i is the thermal expansion coefficient of the different phases in the glass-ceramic, K_i is their elastic modulus, W_i the corresponding weight fractions and ρ_i , their densities. The ability of the glass-ceramic materials to adapt their thermal-expansion characteristics is, hence, a direct consequence of the capability to control the nature and proportion of the crystalline phases present in the final glass-ceramic material.

As is the case for glasses, glass-ceramic materials useful for sealing applications can be classified according to composition, more specifically to the glass forming system.

In addition to devitrifying glasses, glass-ceramics can be obtained from the sintering and crystallization of powders following specific and controlled thermal treatment in order to achieve a final material with the desired microstructure and properties. In this case, all parameters related to the precursor glass powders, such as particle size and shape factor, must also be controlled.

Silicate glass-ceramics

The compositions of silicate glass-ceramics for sealing are mainly based on alkaline silicates, alkaline-earth silicates, zinc silicate, cadmium silicate and lead silicates.

The $\text{Li}_2\text{O}-\text{SiO}_2$ system, with small additions (< 5 wt%) of sodium, potassium, boron, aluminum or zinc, constitute the base of the alkaline silicate glass-ceramics. The addition of P_2O_5 or F^- as nucleating agents induces the crystallization of lithium metasilicate and disilicate together with silica phases or β -spodumene. Depending on the proportions and the nature of the phases present, the resulting glass-ceramics exhibit moderate to high thermal expansions ($\alpha = 8\text{--}19 \times 10^{-6}\text{K}^{-1}$) (McMillan *et al.*, 1966b; West and Glasser, 1970).

Glass-ceramic materials from the $\text{Li}_2\text{O}-\text{ZnO}-\text{SiO}_2$ system were prepared for the first time by McMillan and Partridge (1963). Later studies on this system were undertaken by Chen and McMillan (1985a,b) and Donald *et al.* (1989, 1992). These materials can contain from 30 up to 59 wt% zinc oxide. Normally, P_2O_5 is used as nucleant but the influence of a great number of transition metal oxides on the crystallization, microstructure and thermal expansion characteristics have also been explored. The investigated oxides include TiO_2 , ZrO_2 , HfO_2 , V_2O_5 , Nb_2O_5 , Ta_2O_5 , Cr_2O_3 , MoO_3 , WO_3 , NiO and CuO (Chen and McMillan, 1985b; Donald *et al.*, 1992). The nucleant efficiency considering the activation energy for crystallization is directly related with the field intensity of the metallic cation and it is particularly important for molybdenum, wolframium and vanadium. Applying a standard thermal treatment, the thermal expansion coefficient (α) can vary in the range $(11\text{--}16) \times 10^{-6}\text{K}^{-1}$, depending on the added nucleant species.

The number of papers on glass-ceramics of the $\text{MgO}-\text{ZnO}-\text{SiO}_2$ system is very limited (Metcalf and Donald, 1991). It is well known that the glass forming ability of this system is favored by the incorporation of small additions of Al_2O_3 , together with TiO_2 as nucleating agent. The glass-ceramic materials contain variable proportions of enstatite solid solution, willemite and cristobalite, and their thermal expansion coefficients are in the range $(3.5\text{--}10.2) \times 10^{-6}\text{K}^{-1}$, depending on the crystallization temperature employed.

Glass-ceramics of the $\text{Li}_2\text{O}-\text{PbO}-\text{SiO}_2$ system contain small amounts of Al_2O_3 . The main crystalline phases are lithium and cadmium silicates. Other types of glass-ceramic materials are included in the $\text{PbO}-\text{SiO}_2$ system, which incorporate P_2O_5 and TiO_2 in order to obtain a wide range of thermal expansion coefficients. As mentioned previously, the tendency now is to totally avoid PbO due to its toxicity.

Aluminosilicate glass-ceramics

The aluminosilicate glass-ceramic materials for sealing are mainly based in the systems $\text{Li}_2\text{O}-\text{MO}-\text{Al}_2\text{O}_3-\text{SiO}_2$, $\text{M} = \text{Mg}, \text{Ca}$ or Ba , $\text{ZnO}-\text{Al}_2\text{O}_3-\text{SiO}_2$ and $\text{Li}_2\text{O}-\text{ZnO}-\text{Al}_2\text{O}_3-\text{SiO}_2$, employing TiO_2 , ZrO_2 , or a mixture of both, as nucleating agent.

In the $\text{Li}_2\text{O}-\text{MO}-\text{Al}_2\text{O}_3-\text{SiO}_2$ systems, $\text{M} = \text{Mg}, \text{Ca}$ or Ba , the main developed crystalline phases include, together with silica, solid solutions of β -spodumene, β -eucryptite, β -quartz, cordierite, enstatite, wollastonite, sphene and celsian. Depending on the crystalline phases present, thermal expansion coefficients can range from zero to even negative values to $9 \times 10^{-6}\text{K}^{-1}$ (McMillan and Partridge, 1972).

The preparation of glass-ceramics in the $\text{ZnO}-\text{Al}_2\text{O}_3-\text{SiO}_2$ system, free of alkalines, was developed by Corning Glass Works, employing TiO_2 as nucleating agent. The prepared glass-ceramics presented relatively low thermal expansion coefficients and contain gahnite and rutile as main crystalline phases. Later works in this system were carried out by McMillan and Partridge (1972), Partridge *et al.* (1989a,b) and Vargin and Miklyukov (1968), using TiO_2 as nucleant, and Strand *et al.* (1976) and Holleran and Martin (1987) employing ZrO_2 . Depending on the glass composition and the adopted thermal treatment, it is possible to obtain materials with an α between 3 and $15 \times 10^{-6}\text{K}^{-1}$. The materials with higher thermal expansions contain a significant proportion of cristobalite.

Glass-ceramic materials of zinc aluminosilicate containing lithium as the alkaline oxide have also been prepared. Omar *et al.* (1991) prepared glass-ceramics in the system $\text{Li}_2\text{O}-\text{ZnO}-\text{Al}_2\text{O}_3-\text{SiO}_2$ that contain 13 wt% of Li_2O and up to 28 wt% ZnO . The addition of TiO_2 and ZrO_2 as nucleating agents promotes the crystallization of phases: $\beta_{11}-\text{Li}_2\text{ZnSiO}_4$, $\gamma_0-\text{LiZnSiO}_4$, β -spodumene and β -eucryptite; the corresponding thermal expansion coefficients are in the range $(3.6\text{--}10.0) \times 10^{-6}\text{K}^{-1}$.

Boroaluminosilicate glass-ceramic materials

Zinc boroaluminosilicate glass-ceramics are derived from the corresponding zinc aluminosilicate systems by partial substitution of boron oxide, favoring the crystallization of zinc aluminate, zinc borate and quartz.

Phosphate glass-ceramic materials

Many of the papers on glass-ceramic materials in this system are dedicated to the preparation of biomaterials based on calcium phosphate for their application as implants.

The attention focused on this system as a potential base for the preparation of sealing materials has been limited. Particularly interesting are the works from Wilder *et al.* (1982) on the crystallization behavior of a number of phosphate systems including

$\text{Na}_2\text{O-CaO-P}_2\text{O}_5$, $\text{Na}_2\text{O-BaO-P}_2\text{O}_5$, $\text{Na}_2\text{O-Al}_2\text{O}_3\text{-P}_2\text{O}_5$ and $\text{Li}_2\text{O-BaO-P}_2\text{O}_3$ employing TiO_2 , ZrO_2 , Y_2O_3 , La_2O_3 , Ta_2O_5 , WO_3 and platinum as nucleating agents. The thermal expansion coefficients obtained for these systems are in the range $(16.2\text{--}22.5) \times 10^{-6}\text{K}^{-1}$.

Wang and James (1990) demonstrated that TiO_2 together with Al_2O_3 can be used to promote crystallization in calcium phosphate glasses. The glass-ceramics possess thermal expansion coefficients in the range $(8.6\text{--}14.1) \times 10^{-6}\text{K}^{-1}$.

Additionally, Langlet *et al.* (1992) studied the crystallization behavior of aluminum phosphate glasses and demonstrated that Li_2O , NaPO_3 and AlF_3 can favor crystallization.

A compilation of relevant glass-ceramic compositions for sealing and the important characteristics to be taken into account for a successful seal was published by Donald *et al.* (2011). Additionally, composite materials formed from the mixture of glass or glass-ceramic compositions with ceramic or metallic fillers in order to improve or enhance the sealing material properties is another important field of research.

Glasses or Glass-Ceramics for Sealing - Relative Advantages

The selection of a glass or a glass-ceramic material as a seal depends on the properties that the final application requires and on the thermal characteristics of the system to be sealed.

As well as glasses, glass-ceramics can be easily applied and formed at high temperature while they are in a glassy state. During this first step of the process, the interfacial reactions: glass/metal or glass/ceramic take place, which ensure adherence between the materials to be sealed.

One of the notable advantages of glass-ceramics compared with the corresponding glasses is the possibility to obtain a wide range of thermal expansion coefficients and, in some cases, nonlinear expansion characteristics by means of the control of composition, addition of nucleating agents and the crystallization thermal treatment. As a consequence, the possibility of a better fit between thermal expansion coefficients can be widened with the subsequent improvement of the mechanical stability of the system.

Glass-ceramic materials possess a mechanical resistance often comparable with the corresponding ceramic materials. For those applications in which the mechanical resistance is the major relevant property, glass-ceramic materials have advantages over glasses due to the latter's well-known fragility. In addition, glass-ceramics are more refractory than glasses and in many cases possess higher chemical resistance.

On the other hand, glasses have advantages over glass-ceramics in providing high thermal expansion coefficients and also very low softening temperatures. Relative to processing, sealing with a glass can be carried out in a single step with corresponding savings of time and money while the crystallization step in a glass-ceramic can be slow and complicated and requires more complex technologies.

The Sealing Process

In the sealing process, a series of steps can be considered, each of which determines the final result and the quality of the seal (Mizuhara and Oyama, 1991; Tomsia and Pask, 1991; Moorhead and Kim, 1991; Beauchamp and Burchett, 1991; Sugamuna, 1991; Price, 1984; Dalton, 1956; Kohl, 1967).

Cleaning of the Components

Before the application of the seal, it is essential that the surfaces of the components to be sealed are free of any residual dust, organic matter or grease that can generate gas products during the sealing process. The presence of any dirt can promote the appearance of bubbles or other defects at the same time as reducing adherence between the glass and the material to be sealed. Moreover, glass requires a previous cleaning treatment to eliminate the foreign elements adhered to its surface, especially water vapor. Often, the glass is immersed in an aqueous hydrofluoric acid solution before use.

The cleaning of the components can include different methods from utilization of solvents to vacuum cleaning (Mizuhara and Oyama, 1991; Price, 1984; Dalton, 1956; Kohl, 1967).

Previous Treatments

It is usual, although not always essential, to pre-oxidize the metallic parts before sealing. The pre-oxidation of the metallic elements ensures the further formation by diffusion at the glass-metal interface necessary to achieve gas-tightness of the seal. The mechanical resistance of the interface depends on both the thickness of the oxide layer and its composition.

Application of Glass

An essential step for the achievement of a good seal is application of the glass on the materials to be sealed. The objective of this process is to obtain a thin and uniform layer of glass that, on thermal treatment, provides a seal with a uniform thickness and without defects.

Different techniques have been tested for applying the glass. Depending on the method, it is possible to start using melted glass, glass powder or a preform.

Preform

The use of a preform is quite common with sealing glass-ceramic materials and especially when an intermediate glass is applied to ensure adherence and a good fit of thermal expansion coefficients (Mizuhara and Oyama, 1991). The preform is located between the materials to be sealed and is fixed to them during the thermal treatment by means of, for example, a graphite mold.

Glass injection

The melted glass is injected, under pressure, between the components to be sealed that are held in place with the help of a mold. The simultaneous application of vacuum at the opposite end of the mold improves the glass fluidity, facilitating the elimination of the trapped gases and ensuring perfect fit of the glass and the surfaces to be sealed. Moreover, it is a fast process and easy to automate.

Use of agglomerants

One of the most employed procedures starts from the milled glass, mixed with an agglomerant such as amilacetate or nitro-cellulose. The mixture, in the form of a paste or cement, is easily applied on the surfaces to be sealed employing diverse techniques. It is a simple process that allows the glass thickness to be easily controlled but has the inconvenience of the high proportion of solvents and organic matter that are introduced. The technique requires a careful further thermal treatment to eliminate the rest of the agglomerant material employed.

Sedimentation

Pliskin and Conrad (1964) used a sedimentation technique designed to obtain a uniform layer of glass powder on a substrate. The uniformity of the glass layer depends of the dielectric constant of the employed media. In low dielectric constant media, the glass particles tend to agglomerate in the suspension and deposit forming a rough surface. In high-dielectric constant media, the deposited layer is rather uniform on its surface but tends to be thicker towards the substrate borders. Pliskin and Conrad improved the technique using both media of high and low dielectric constant in double layers depositing a flat and uniform glass onto the substrate. The glass layer deposited on the substrate is heated up to temperatures slightly higher than the glass softening point to form a film. By means of this technique, thicknesses of 1.50 μm can be obtained with a difference in thickness between the different layers of $\pm 0.03 \mu\text{m}$ and an average variation through the same layer of 0.06 μm .

Immersion

The technique of immersion, described in Dalton (1956) first patents, is a useful procedure to seal metallic components of different dimensions. The materials to be sealed are immersed in the glass melt and once extracted they preserve a thin glass film that seals by compression.

A modification of this procedure is the use of a preheated iron tip to extract the glass by immersion in the melt. The tip is heated to a temperature higher than the softening temperature so the sealing glass flows from the tip onto the part to be sealed.

Pulverization

Sealing by pulverization of the preheated pieces to be sealed, with sealing glass powder, has been described by Dalton (1956). A uniform glaze is firstly obtained on the surfaces that finally seal during thermal treatment under mechanical load. Better results are obtained when starting from preheated powder at 200–300°C.

Tape process

The sealing technique by tape, also suggested by Dalton (1956) has been used in areas such as the metallization of ceramic parts in ceramic-metal seals or in the sealing of optical cells or lasers. Although the sealing glasses for tape processing have been commercially available for long time, the literature on its utilization is scarce. Additionally, this technique presents the inconvenience of its high cost.

Thermal Treatment

Once the glass has been applied on the materials to be sealed, the whole system undergoes a heating process under load; normally a reducing or neutral atmosphere is preferable (Tomsia and Pask, 1991).

The first step of thermal treatment requires slow heating, especially if the applied glass has been mixed with an agglomerant in order to eliminate the organic matter and traces of the employed solvents. After stabilization at a low temperature, the glass is subjected to a temperature suitable for optimum glass flow and wettability and, at the same time, the excess of glass is eliminated and only a thin glass layer between the components is retained. In glasses of certain composition, their devitrification can be induced by means of a suitable thermal treatment. Finally, the joint is slowly cooled down to room temperature to avoid the appearance of mechanical stresses.

When the material constituting the seal is a glass-ceramic, the thermal process will include heating up to a temperature high enough for the glass to flow followed by a nucleation process at lower temperature, and finally a crystallization process at more elevated temperature.

Most of the mentioned methods use the approach of conventional sealing in a furnace. Laser welding is an alternative sealing technology that will not be discussed here but detailed information and references can be found in [Pablos-Martín et al. \(2020\)](#).

Adherence of the Seal - Bonding Theories

The nature of the bonding between a glass and a metal has been the subject of considerable controversy and the relevant factors have gradually emerged. A certain number of theoretical approximations tend to elucidate the main factors determining the adherence between a metallic or ceramic substrate and a glass and the conditions that must be given to achieve a good chemical bonding at the interface.

Thermodynamic Approach

From the practical point of view, the first condition to obtain a seal or glass-metal coating is that the glass wets the metal surface and, as a consequence, spreads on it.

When a liquid comes into contact with a solid, a new interface is created, and the liquid may or may not spread on it. According to thermodynamics, the liquid will spread only if the energy resulting from the new solid-liquid interface is smaller than the corresponding solid-vapor interface. The greater this difference in energy, the greater is the extension of the contact surface between the liquid and the solid. The driving force of the wetting process is then related to the difference in energy between the solid-vapor and solid-liquid interfaces. Nevertheless, since the configuration with the lowest superficial energy is a sphere, there is an additional force that resists spreading of the liquid on the solid surface. This behavior is often studied as a function of the contact angle between the drop of liquid and the solid ([Donald and Cahn, 1993b](#); [Beauchamp and Burchett, 1991](#)) ([Fig. 4](#)). The drop shape is a function of three energy terms, as described by Young's classical equation:

$$\gamma_{sv} = \gamma_{sl} + \gamma_{lv} \cos \theta \quad (2)$$

where γ_{sv} , γ_{sl} and γ_{lv} are the interfacial energies of the solid-vapor, solid-liquid and liquid-vapor interfaces, respectively.

A liquid will wet a solid ($\theta < 90^\circ$) when the energy of the system diminishes as a consequence of the formation of the solid-liquid interface. The greater the degree of wetting, the smaller the angle θ will be. Of course, no liquid will exhibit the maximum contact angle of 180° , even in the case that the liquid does not wet the solid due to the distorting influence of gravity on the liquid droplet.

Fig. 4 Sessile drop configurations for the situations of: a) liquid wetting a solid, and b) liquid not wetting a solid. After Pascual, M.J., Pascual, L., Durán, A., 1997. Vidrios y vitrocerámicos para soldadura: usos tradicionales y nuevas áreas de aplicación. Boletín de la Sociedad Española de Cerámica y Vidrio 36 (4), 383–398.

The concept of work of adhesion, W_A , was introduced by Dupré (1869): the work of adhesion is equal to the decrease of free energy produced as a consequence of the creation of a new interface. The relationship between the work and the superficial energies can be expressed by the equation:

$$W_A = \gamma_{sv} + \gamma_{LV} - \gamma_{sL} \quad (3)$$

An interface will be stable if W_A is positive, when the formation of the interface lowers the free energy of the system. Introducing the contact angle, the relevant equation is:

$$W_A = \gamma_{sv}(1 + \cos\theta) \quad (4)$$

It is possible to experimentally obtain quantitative values of the bond strength and the behavior of different glass/metal systems.

Although the thermodynamic approximation must be carefully treated, it can be used as a first approximation in order to know if there are favorable conditions in a given system.

One of the first conclusions that can be extracted is that if the liquid has a lower surface energy than the solid substrate, the system can diminish its energy by means of the extension of the liquid phase on the solid surface, so the liquid wets the solid. However, this conclusion may be incorrect since it can suggest, for example, a change in the solid surface diminishing both its energy and wettability (Beauchamp and Burchett, 1991; Loehman, 1989).

The simple thermodynamic approximation does not assume reaction between liquid and solid. If there is a chemical reaction at the interface that generates a new product, the associated drop in free energy can promote adhesion (King, 1933). The introduction of the new terms leads to the equation

$$W_A = \gamma_{LV}(1 + \cos\theta) + \gamma_{Ri} - C\Delta G^\circ \quad (5)$$

where γ_{Ri} is the interfacial energy between the solid and the reacting interfacial layer, ΔG° is the Gibbs free energy for the new interfacial compound formation and C is a constant.

A spontaneous reaction is characterized by a negative value for ΔG° that increases W_A and diminishes θ . In order to know the most probable reactions under bonding conditions, ΔG° can be calculated from the available thermodynamic data. The reactions with more negative ΔG° values will be thermodynamically more favored, although the derived data must again be treated with precaution when a given reaction may not be kinetically favored.

Mechanical Bonding

In principle, the adherence between an enamel and a metallic substrate was believed to have its origin in mechanical type phenomena. These theories have a wide acceptance due to the fact that the interface between a metal and a porcelain enamel often appears rough, even with an initially flat substrate. It was thought that the bonding between the rough substrate and the glass was a consequence of a purely mechanical effect, and two theories appeared that try to explain the mechanisms through which this roughness could be generated.

Dendrite theory

This theory is based on the observation of metallic dendrites that appear in the interfacial region after sealing a glass to a metal (King, 1933; Healy and Andrews, 1951; Khachatryan *et al.*, 2019). These metallic dendrites are suggested to be responsible for the adherence, acting as cleavage points between the metallic substrate and the glass.

The dendrites could form as a consequence of the reaction between a metallic oxide present in the glass with a metallic element in the substrate. For example, when a glass containing CoO is used for sealing an iron substrate, the following reaction can take place:

The dendrites of metallic cobalt would, thus, be responsible for the adherence between the glass and iron substrate.

Electrolytic theory

The electrolytic theory proposes that the roughness of the metallic substrate is produced during the glass application, due to the electrolytic type or galvanic corrosions (Staley, 1934; Richmond *et al.*, 1953; Moore *et al.*, 1954). For example, the bonding between a glass containing CoO with an iron substrate in air results from the precipitation of the metallic cobalt as proposed by the dendrite theory. Nevertheless, it was thought that those precipitates formed by contact between the glass and iron substrate constituted the basis of the localized electrolytic or galvanic cells. The net effect was the dissolution of iron into the glass and the formation of a pitted surface on which the glass could flow between the voids. The process could take place as follows:

Nevertheless, the presence of more reducible oxides that should originate in a rougher substrate does not lead to stronger bonding.

Mutual Solubility and Formation of Intermediate Compounds

Other mechanisms for stabilizing bonding between a metallic substrate and a glass is by means of the formation of a chemical compound or a transition interface. The oxide layer on the metal generally formed by pre-oxidation can be dissolved in the glass, forming an intermediate layer progressively richer in the metallic oxide. Alternatively, the bonding could be obtained through the formation of an intermediate compound that joins the glass to the metallic or oxide surface. This theory is very much related with thermodynamic and chemical approximations, and it is possible to predict the formation of a compound.

Chemical bond

From a chemical or molecular point of view, the bond can have a transition zone in which the metallic bond of the substrate is gradually substituted by an ionic-covalent bond of the glass.

King (1933) proposed the formation of a strong chemical bond at the glass/metal interface in conditions in which the glass is saturated with an oxide of the metallic substrate. When the oxide of the metal is dissolved into the glass up to saturation, the metallic ions remain at the surface promoting the metal-metal bond through the interface. At elevated temperatures, when the metallic ions in the glass and the atoms of the metallic substrate are relatively mobile, a continuous exchange at the glass-metal interface will take place, establishing a dynamic equilibrium that could remain if the glass is not saturated with the oxide. At low temperatures, when the mobility of the atoms and ions is lower, an electronic exchange at the interface may exist, and ions and atoms can alternate in properties depending on the concentration of electrons or the degree of ionization. The atoms and ions of intermediate character can constitute the transition between the metallic and ionic-covalent states, assuming that the saturated state of the interface is maintained. The solubility of the metallic oxide and, in turn, the bond strength can be modified changing the glass composition. For example, when sealing iron and glass, the solubility of FeO into the glass increases with increasing proportion of forming oxides, such as silica or boron oxide, and diminishes with the incorporation of modifier oxides.

When the metallic substrate does not present an oxide layer or the pre-oxidized layer dissolves without reaching saturation, certain redox reactions between the metal and the glass must take place to achieve or maintain the proper conditions for establishing a chemical bond. The reaction between a glass and a metallic substrate free of oxide would occur in this case through a two-step mechanism. At first, a redox reaction takes place that leads to the formation of an oxide layer on the metal at the interface. Second, the dissolution of this oxide into the glass takes place. The saturation at the interface can be achieved even in the absence of an oxide layer formed by pre-oxidation. Nevertheless, if the reactions between a glass and a metal are not thermodynamically favorable (if the value of ΔG° for oxide formation is positive), the reaction will not proceed spontaneously under normal conditions. In this case, the reaction can only progress if the conditions of the sealing process are modified. As an example, for sealing an iron substrate without oxide layer with a sodium silicate, the following reaction was proposed (Tomsia and Pask, 1990; Pask and Tomsia, 1981; Pask, 1987a,b; Kramer and Massey, 1984; Partridge, 1990):

The global free energy for this reaction can be written as follows

$$\Delta G = \Delta G^0 + RT \ln \frac{[a_{\text{FeO}(\text{interface})} \cdot x a_{\text{Na}}^2]}{[a_{\text{Fe}} \cdot x a_{\text{Na}_2\text{O}(\text{glass})}]} \quad (11)$$

where a is the chemical activity of each component.

Under normal conditions, the chemical activities are equal to one, and $\Delta G = \Delta G^\circ$. If ΔG° is positive, the reaction will proceed spontaneously. Nevertheless, it can also proceed if the value of the activity quotient is less than one. This situation can happen if, by means of control of the process parameters, a low sodium partial pressure, a low activity for FeO and a high activity for Na_2O can be guaranteed.

From the point of view of the formation of a chemical bond, it is necessary to highlight the role of so-called adherence promoters. These are oxides of easily reducible metals which are able to react with the metallic substrate ensuring the maintenance of saturation conditions, e.g., cobalt or nickel oxides when sealing on iron substrates. If, during the sealing process, the complete dissolution of the oxide layer coming from the pre-oxidation of the substrate into the glass takes place, the metal iron will come in contact with the glass, reducing the adherence promoter oxide, forming more of the substrate oxide and enhancing adherence. In this way, the interfacial saturation with the substrate in the oxidized state is ensured during sealing. Donald *et al.* (2008) describe this process in more detail.

Applications

Conventional applications

Glass/metal and glass-ceramic/metal seals have found a wide range of applications in electronics and engineering. Glass is a quasi-ideal material for this type of application due to its ability to form hermetic and mechanically strong joints with metals and to be impermeable versus gases, a good electrical insulator, reasonably refractory and a low-cost material.

Fig. 5 Example of sealed metal pieces. Courtesy of Vactron S.A, <https://www.vac-tron.es/en/multi-lead-feedthrough.html>). The glass sealants are used for the fabrication of filaments, pyrotechnics, sensors, micro-sensors, etc.

Traditionally, the field of application of sealing glasses has extended to the fabrication of incandescent and vapor lamps, vacuum tubes, radar magnetrons and microwave connectors, TV tubes, switches, high pressure sodium lamps, magnetic recording heads and high-voltage supplies. In a wide sense, the field also includes porcelain enameling and coatings for high-temperature or mechanical protection.

In composite structures, such as lamps and electron tubes, glass is used because it transmits light, can easily form useful shapes, provides electrical insulation, and is chemically inert versus corrosive and oxidizing environments. The glass and the metal can also be joined with organic adhesives or metallization and soldering techniques, although they are less frequently used.

Glass-ceramic/metal seals are a more modern technology used for more complex applications. [McMillan et al. \(1966a,c\)](#) were the first to show that glass-ceramics could be employed to produce seals exhibiting superior properties compared with glass/metal seals. Some of the applications of the glass-ceramic/metal seals include tube covers for laser and refractory vacuum tubes, vacuum switches, high-temperature insulation and high pressure pyrotechnic actuators ([Nash et al., 1983](#); [Tummala, 1991](#)).

In the field of image reproduction, the development of devitrifiable glasses for sealing made the fabrication of color TV tubes possible. In planar visualization systems, such as the visualization panels for gas discharge, the sealing glass has a protective role in addition to a sealant, maintaining a narrow and precise spacing between the flat glass sheets that constitute the screen.

The complexity and sensitivity of silicon microelectronic systems has notably increased in parallel with the demand for new sealing glasses for sealing at low temperature. Glasses of the $\text{PbO-ZnO-B}_2\text{O}_3$ system, with a high lead content and softening temperature below 300°C have permitted alumina pieces used for the encapsulation of these systems to be sealed. The glass acts as a sealant between two alumina plates. Other glass systems have been explored for this application such as borates and phosphates, as well as composite materials. Additionally, glass-ceramic materials have been identified as possible candidates for the encapsulation of advanced systems in substitution of alumina. A wide review of the applications of substrates and glass-ceramic coatings on metals applicable in microelectronics in substitution of alumina has been published by [Partridge et al. \(1989a,b\)](#). Glass-ceramics of the systems $\text{Li}_2\text{O-Al}_2\text{O}_3\text{-SiO}_2$ (LAS), $\text{ZnO-Al}_2\text{O}_3\text{-SiO}_2$ (ZAS) and $\text{MgO-Al}_2\text{O}_3\text{-SiO}_2$ (MAS), prepared by bulk nucleation or powder sintering, are compatible with thin and thick layer microelectronics and can be used in a great variety of applications. The metallic substrates covered with a glass-ceramic offer the advantage of good thermal dissipation, which is necessary when the packing density of the circuit components is high. Glass-ceramics of cordierite combined with copper are currently used by IBM due to the low dielectric constant of cordierite and the good fit with the thermal expansion coefficient of silicon ([Fig. 5](#)).

New applications

The reliable joining of Ceramic Matrix Composites (CMCs) using glasses and glass-ceramics is a key technology for their use in applications characterized by harsh environmental conditions, such as energy production, aeronautics, aerospace, etc. where large and complex geometries are involved and it is a work in continuous development ([Ferraris et al., 2020a](#)).

On the other hand, new compositions have been developed for the preparation of stable glass-metal seals with titanium and titanium alloys for use in components such as the heads of batteries. Some compositions have been patented, for example compositions containing CaO , Al_2O_3 , B_2O_3 , SrO and BaO ([Brow and Watkins, 1992](#)). Research involving Ti-6Al-4V has also been reported ([Staff et al., 2016](#)).

Nevertheless, the most recent application for sealing glasses still under development is related with power generation systems: gas separation membranes ([Lundin et al., 2017](#)), lithium and sodium batteries ([Brow and Watkins, 1991](#); [Smeacetto et al., 2017](#); [Manthina et al., 2019](#)), molten carbonate fuel cells (MCFC) ([Williams et al., 1993](#); [Izaki et al., 1993](#); [Ohtsuti et al., 1993](#); [Ota, 1997](#); [Mugikura et al., 1998](#); [Terada et al., 1999](#); [Pascual, 2000](#)) and solid oxide fuel cells (SOFC) ([Fergus, 2005](#); [Mahapatra and Lu, 2010](#); [Blum et al., 2011](#); [Haanappel et al., 2005](#); [Buchkremer and Conradt, 2010](#); [Cela Greven, 2015](#); [Yana et al., 2019](#); [Rodríguez-López, 2016a](#)). In particular, the field of sealing glasses for SOFC has led to about 600 papers (source Scopus) and numerous patents in the literature. Especially relevant are the pioneering works of Rolla, PNNL, RWTH-Aachen and FZ-Jülich.

Fig. 6 Union Crofer22APU-glass-ceramic-8YSZ of composition 10B(Sr) sealed at 850°C for 10 h. (A) General view. (B) Steel-sealant interface. (C) Sealant-8YSZ interface. After de Pablos-Martín, A., Rodríguez-López, S., Pascual, M.J., 2020. Processing technologies for sealing glasses and glass-ceramics. *International Journal of Applied Glass Science* 11 (3), 552–568.

In most of these applications, the glass must work at high temperature in a very corrosive environment and undergo thermal cycling. **Fig. 6** shows a typical joint Crofer22APU-glass-ceramic-8YSZ present in a SOFC. The glass-ceramic shows a good densification and good bonding with both steel and YSZ. Most current research on sealing materials deals with improvement of their thermomechanical behavior and self-healing ability and there is still ample margin to investigate and optimize compositions, processing and properties (Ferraris *et al.*, 2020b).

Glasses and Glass-Ceramics for Nuclear Waste Immobilization

Daniel Caurant and Odile Majérus, Chimie ParisTech, PSL Research University, Paris, France

© 2021 Elsevier Inc. All rights reserved.

Introduction

As in all other industries and human activities, the nuclear industry generates waste during energy production (electricity) or weapons fabrication. However, in the case of nuclear industry some of these wastes are highly radioactive and must be isolated durably from the biosphere in highly durable matrices for several thousands of years or more in order to limit their potential impact on the environment (Jantzen *et al.*, 2011; Vernaz *et al.*, 2012; Pegg, 2015). This is different from the case of certain types of non-nuclear hazardous industrial or domestic waste that can be recycled to make useful materials (glasses, glass-ceramics) that severely limit the rate of release of toxic elements (heavy metals) in the environment (Colombo *et al.*, 2003; Donald, 2007, 2016).

In commercial nuclear power reactors, the burn up of ^{235}U enriched UO_2 fuel under thermal neutrons produces energy due to the fission of uranium nuclei and generates a wide spectrum of fission products (Table 1), and actinides by neutron capture (plutonium and other actinides).

Several countries such as the US, Canada and Sweden decided not to reprocess their spent nuclear fuel leaving it in interim storage while waiting for possible disposal (open fuel cycle), whereas for several decades other countries such as France, Russia, the UK and Japan reprocessed their spent nuclear fuel to recover remaining uranium and plutonium to prepare new nuclear fuel (MOX fuel, mixed oxide fuel consisting of Pu mixed with natural uranium, reprocessed uranium, or depleted uranium) and also to reduce the radiotoxicity of the ultimate waste containing the fission products and minor actinides (closed fuel cycle) (Wilson, 1996; Rodríguez-Penalonga and Moratilla Soria, 2017). Indeed, spent nuclear fuel may still contain about 96 wt% of reusable material (U + Pu) to produce energy. The ultimate high level radioactive waste (HLW) recovered after the reprocessing of spent nuclear fuel coming from energy production (commercial waste) and also that coming from plutonium weapons fabrication referred to as defense waste (Metcalf and Donald, 2013) are today conditioned by dissolution at the atomic scale in highly durable glassy or partially crystallized matrices (Ojovan and Lee, 2007; Caurant *et al.*, 2009; Jantzen, 2011; Vernaz *et al.*, 2012; Donald, 2016; Jantzen and Ojovan, 2019). In these wasteforms, the glassy and crystalline phases play the role of solvent for almost all the species – radioactive or not – initially present in the waste (Fig. 1). Several other nuclear waste generally less radioactive (low or intermediate radioactive level waste) than the reprocessing waste originating for instance from nuclear installations dismantling or other sources could also be immobilized in glassy matrices (Sobolev *et al.*, 2005; Cantrel *et al.*, 2015; Girolid *et al.*, 2018; Achigar *et al.*, 2021).

In this chapter, after considering the nature and composition of HLW, and the specifications of an efficient wasteform to incorporate these wastes, the focus will be on the vitrification processes performed by melting the mixture of a glass frit with waste, and on the way several problematic elements present in the waste such as cesium, technetium, molybdenum, zirconium, lanthanides and actinides can be incorporated into the structure of glasses (such radioactive wasteforms are generally called nuclear glasses or nuclear waste glasses). The effect of glass composition changes on the incorporation of some of these elements (solubilization, demixing in the melt, crystallization) will also be considered by focusing on alkali-lime aluminoborosilicate type wasteforms that represent the main type of nuclear glasses used worldwide for HLW containment. The case of waste incorporation in glass-ceramics that can be envisaged to immobilize non-separated HLW or separated long-lived radionuclides will also be developed. After an interim storage period, all these conditioned wastes will have to be kept by geological disposal in a deep underground repository following a multiple barrier containment approach (Ewing *et al.*, 2016; Grambow, 2016; Laverov *et al.*, 2016) where the glassy or partially crystallized wasteforms will constitute the first containment barrier. The long-term behavior against water alteration and self-irradiation of nuclear glasses will also be addressed.

Nature of Highly Radioactive Waste and Need for Their Immobilization

HLW generally contain high amounts of α , β and γ radionuclides which are particularly harmful to the living world, even if radioactivity also exists in nature (^{235}U , ^{238}U , ^{232}Th , ^{40}K). They are produced in nuclear reactors, the aim of which is to produce electricity or plutonium for military purposes. In both cases, nuclear fuel is subjected to a neutron flux leading to the production of energy (and then electricity for power reactors) and the formation of fission products (FP, Table 1) and minor actinides (MA: Np, Am, Cm) generated by neutron capture mainly by ^{238}U (as for Pu formation) that constitute very dangerous (highly radioactive and toxic) non-reusable ultimate wastes. These wastes represent only around 4 wt% (comprising mainly FP and 0.1 wt% MA) of the spent fuel for power reactors.

In the context of nuclear weapons, spent fuel is reprocessed by dissolution in acid solutions to recover plutonium (Metcalf and Donald, 2013). Civilian spent fuel can be reprocessed in the same way (Purex process), in order to recover the uranium and plutonium remaining in the spent fuel (about 96 wt%) to prepare new nuclear fuel (Wilson, 1996; Bonin, 2008; Nuclear Energy Agency, 2018). In both cases, the remaining ultimate HLW that are present as concentrated aqueous nitric solutions are stored during long periods in metallic tanks to enable a significant decrease of their radioactivity and thermal power before conditioning.

Table 1 Main families of fission products occurring in spent nuclear fuel before reprocessing. The values given in this table correspond to that of a UO_2 spent fuel enriched with 3.5% ^{235}U (burn-up 33 GWday t^{-1} in a pressurized water reactor, 3 years after discharge) given in kg by ton of U before burning. It can be remarked that rare earths (Y + lanthanides) constitute the most abundant family of fission products in wt%. More than 300 radionuclides (β , γ emitters) are produced during fuel burn-up but more than 60% of them will have disappeared several times after spent fuel discharge. Nearly 40 elements of the Mendeleyev classification from Ge to Dy are generated during fission reactions

Chemical family	Weight (kg/U)
Rare gases (Kr, Xe)	5.6
Alkalis (Cs, Rb)	3
Alkaline-earths (Sr, Ba)	2.4
Rare earths (Y, lanthanides)	10.2
Transition metals (Mo, Zr, Tc)	7.7
Chalcogens (Se, Te)	0.5
Halogens (I, Br)	0.2
Noble metals (Ru, Rh, Pd)	3.9
Others (Ag, Cd, Sn, Sb...)	0.1

Note: Boullis, B., Devezeaux de Lavergne, J.-G., 2006. The treatment of spent fuel: A well-controlled sector. Clefs CEA 53, 19–25. (in French).

Fig. 1 Structural scheme showing the way fission products such as neodymium (one of the most abundant lanthanides present in HLW, Fig. 3) may enter into the structure of a peralkaline borosilicate nuclear glass. Nd^{3+} ions may be located in the depolymerized regions (DR) of the glass structure that are rich in non-bridging oxygen atoms (NBOs) and alkali + alkaline-earth cations (here Na^+ and Ca^{2+}). In these regions, NdO_n polyhedra can be locally charge compensated by alkali + alkaline-earth cations. Polymerized regions (PR) rich in bridging oxygen atoms (BOs) are also shown.

Depending on the type of nuclear reactor, fuel and cladding nature, on the fuel composition and burn-up, and on the particularities of the extraction processes, the composition of HLW may strongly vary between countries and within the same country over time. For instance, the concentrations of FP are relatively low in the HLW solutions, originating from the reprocessing of defense spent fuels or civilian spent fuels using natural uranium (0.7% ^{235}U), because of their low burn-up in comparison with the HLW solutions originating from pressurized water reactors (PWR) using ^{235}U -enriched fuel (Donald *et al.*, 1997; Donald, 2016), because the amount of FP increases proportionally with the burn-up of the fuel. As they contain long-lived α and β radionuclides for which half-lives can reach thousands to millions of years (MA, ^{135}Cs , ^{99}Tc , ^{93}Zr ...), HLW must be isolated from the biosphere from thousands to hundreds of thousands of years, at least until their radiotoxicity level drops back to the radiotoxicity level of the initial uranium ore (Fig. 2).

Fig. 2 Changes with time of the potential radiotoxicity (expressed in Sv/ton of initial uranium metal) of a UO_2 enriched spent fuel with 3.5% of ^{235}U from a power reactor (burn-up 33 GWd t^{-1} and 3 years after discharge) showing the contribution of plutonium, uranium, minor actinides (MA) and fission products (FP). The level of radiotoxicity of the initial natural uranium ore (UO_2) taking into account ^{235}U enrichment is indicated for comparison (horizontal line). The vertical dotted line indicates the time needed for MA to reach a radiotoxicity level close to that of the initial ^{235}U -enriched fuel. It clearly appears that after plutonium extraction from the waste (reprocessing), the most problematic long-term radionuclides are MA. After reprocessing (Pu and U extraction), the main contribution to the potential radiotoxicity will be due (during 2–3 centuries) to the short-lived β -emitters such as ^{137}Cs and ^{90}Sr (FP) and then to the long-lived α -emitters such as ^{241}Am , ^{243}Am and ^{244}Cm (MA). Modified from Bardez, I., 2004. Study of the Structural Characteristics and Properties of Glasses Rich in Rare Earths Intended for the Immobilization of Fission Products and Long-lived Elements. (Ph.D. thesis). University Pierre and Marie Curie Paris. (in French). Available at: <https://pastel.archives-ouvertes.fr/pastel-00001075>.

Immobilization of Highly Radioactive Nuclear Waste

HLW solutions originating from spent nuclear fuel reprocessing contain FP, MA and also additional non-radioactive but relatively abundant elements coming from the Purex process (P, Na) and from the corrosion of the tanks (Fe, Ni, Cr) in which are kept HLW solutions (Fig. 3). Because of the risks of diffusion and dispersion of these wastes in the biosphere and also to facilitate their transport and storage, they must be conditioned in solid and highly durable matrices before deep underground disposal. Nowadays, all the elements present in HLW solutions are immobilized together in the same matrix, but numerous studies have been carried out in order to selectively extract from these solutions the most active and long-lived α or β radionuclides such as MA and Cs (^{135}Cs half-life of 2.3 million years) using enhanced reprocessing processes with appropriate extracting molecules (Madic *et al.*, 2002; Bonin, 2008) and then to find specific very durable wasteforms for these separated radionuclides (Caurant *et al.*, 2009). For instance, many works have been carried out on highly durable ceramic (zirconates, phosphates, titanates) and also on glass-ceramic matrices for the specific immobilization of MA (Guy *et al.*, 2002; Caurant *et al.*, 2009). Similar types of studies have also been conducted on ceramics, glasses and glass-ceramics for the immobilization of plutonium-rich waste (Muller and Weber, 2001; Zhang *et al.*, 2017). The possibility to immobilize long-lived ^{129}I (half-life of 15.7 million years) in glassy and ceramic matrices has also been investigated, iodine being recovered separately during spent fuel dissolution in nitric solutions (Lemesle *et al.*, 2014; Riley *et al.*, 2016; Yang *et al.*, 2017).

Because of its low chemical durability, its high thermal power (due to the high concentration of thermal radionuclides) and its high specific area, the solid calcine that can be obtained after water evaporation and calcination of HLW solutions is not itself an efficient wasteform without the addition of other elements (such as Si, B, Al, alkalis and alkaline-earths for borosilicate glassy wasteforms). It can only be considered as an intermediate product that must be immobilized by dissolution or dispersion (by partial or total encapsulation) in a more durable solid matrix. When looking for an efficient wasteform for HLW containment, several important points must be considered concerning both the properties of the final matrix and the difficulties that can be encountered for its synthesis in radioactive environment (Caurant *et al.*, 2009; Jantzen and Ojovan, 2019). For instance, concerning the properties of the matrix:

- (1) The matrix must incorporate almost all the elements (radioactive or not) of the wastes with a sufficiently high loading to limit the volume of the wasteform (high incorporation capacity) while taking into account the heating generated by radionuclides disintegration - such as ^{137}Cs , ^{90}Sr , ^{241}Am and ^{244}Cm - that could affect matrix structure and microstructure and could be problematic for storage and disposal (increase of the minimum distance between canisters).
- (2) The matrix must exhibit very good long-term behavior concerning both its resistance against alteration by water (liquid and vapor) and its resistance against self-irradiation. Even if structural evolution occurs specially under the effect of α -decays, the chemical durability and the capacity of the matrix to retain radionuclides must remain acceptable.

Fig. 3 Relative abundance (in wt% of oxides) of the different families of elements present in HLW solutions originating from the reprocessing of an UO_2 enriched (3.5% ^{235}U) spent fuel (see details in the legend of Table 1).

Concerning the synthesis of the wasteform:

- (1) The process to incorporate the wastes into the matrix must be as simple as possible and the number of steps must be small in order to avoid the production of high amounts of secondary radioactive wastes and to reduce the cost of immobilization.
- (2) The temperature of synthesis must not be too high to limit the risks of evaporation and to take into account furnaces and canisters limitation.

To meet these requirements, numerous kinds of glasses, glass-ceramics and crystalline (single phase or multiphase) matrices have been envisaged (Hench *et al.*, 1986; Donald *et al.*, 1997; Donald, 2007; Lee *et al.*, 2006; Caurant *et al.*, 2009; Jantzen and Ojovan, 2019). Nevertheless, because of their ease of synthesis (melting + casting), their high loading capacity related to their structural flexibility and lack of stoichiometry facilitating waste incorporation, their very good self-irradiation resistance and good chemical durability, glassy matrices still represent today the main type of matrix implemented on an industrial scale since 1978 to immobilize HLW (Vernaz *et al.*, 2012; Ojovan and Lee, 2010; Gin *et al.*, 2017b). In glassy wasteforms the majority of the elements coming from HLW may adapt, more easily than in crystalline phases, their local environment according to their size, their ionic charge and the amount of non-bridging oxygen atoms (NBOs) and charge compensators available in glass composition (see Fig. 1 for Nd^{3+} ions incorporation in a borosilicate glass). Nevertheless, many studies have been performed to develop matrices consisting of a glassy phase and one or more durable crystalline phases able to incorporate wastes in their structure and a current tendency is to accept partial crystallization in glassy matrices to reach higher waste loading, if it is not detrimental to the containment properties of the wasteform (Caurant *et al.*, 2007b; Crum *et al.*, 2012) (Fig. 4).

In comparison with glassy wasteforms, due to their lower structural flexibility associated with long range order and their more complex preparation (grinding + pressing + sintering steps), single phase ceramic matrices are not well adapted to incorporate the wide spectrum of elements with different sizes and charges present in HLW solutions (Fig. 3). They are more adapted for the containment of specific radionuclides (MA, Pu, Cs) (Aubin-Chevaldonnet *et al.*, 2007; Wang and Liang, 2012; Orlova and Ojovan, 2019). Indeed, the composition and the structure of such matrices must be selected according to the crystallographic sites available to immobilize the elements from the waste. Nevertheless, even if their synthesis appears more complex than that of glasses, multi-phase ceramics such as the Synroc ceramics containing different highly durable crystalline phases each adapted to immobilize different groups of the elements present in HLW or in actinide-rich waste have been envisaged (Gregg and Vance, 2016).

Vitrification of Highly Radioactive Nuclear Waste

Nowadays, HLW recovered from civilian and defense spent fuel reprocessing are incorporated by dissolution into the structure of borosilicate or aluminophosphate glasses melted in ceramic or metallic melters at temperatures not exceeding 1100–1150°C and cast in metallic containers to obtain large glass blocks (~400 kg) before interim storage, using continuous melting processes industrialized over more than 40 years (Vernaz *et al.*, 2012). Because of the lack of sufficient glass formers, fluxing agents and charge compensators in HLW compositions (Fig. 3), it is necessary during melting to add to the waste a high proportion (~70–80 wt%) of a glass frit (supplied by a glassmaker) to provide the glass former (SiO_2 , B_2O_3 , P_2O_5), intermediate (Al_2O_3) and modifier (Na_2O , Li_2O , CaO) oxides necessary to form the glassy network (Fig. 1) and to enable the dissolution in this structure of the elements coming from the waste (Fig. 5).

Using a pre-prepared glass frit to mix with the waste rather than a mixture of raw materials (oxides, carbonates...) as classically done in the commercial glass industry enables a large amount of melt able to dissolve the waste to be obtained more rapidly during heating. Moreover, this also avoids the generation in a radioactive environment of gases such as CO_2 coming from the raw

Fig. 4 Back-scattered SEM image and EDX cartography of a partially crystallized borosilicate glass developed for the immobilization of Mo- and P-rich HLW waste. The EDX cartography shows the distribution of the elements in the large crystallized droplet located in the center of the image. Effect of molybdenum on the structure and on the crystallization of $\text{SiO}_2\text{-Na}_2\text{O-CaO-B}_2\text{O}_3$ glasses. *J. Am. Ceram. Soc.* 90, 774–783, with permission from John Wiley and Sons.

Fig. 5 Example of a borosilicate glass frit (right), calcined inactive waste (left) and inactive nuclear borosilicate glass (top) that can be synthesized at lab-scale to test glass frit formulation. Because of the high amounts of elements present in the waste that absorb in the visible domain (transition metals, lanthanides), the glass has a black color.

materials. The choice of the composition of the glass frit results from a compromise between its incorporation capacity and its reactivity with the waste during melting which limits the waste loading ($\sim 18\text{--}35\text{ wt\%}$), the properties of the melt (viscosity) and its low liquid-liquid phase separation and crystallization tendency during cooling in the canister (the cooling rate is close to $1^\circ\text{C}/\text{min}$ in the bulk of glass blocks), and the properties of the final wasteform (long-term behavior) as explained above. For instance, the crystallization of poorly durable phases likely to incorporate radionuclides or of SiO_2 and Al_2O_3 -rich phases such as nepheline ($\text{NaAlSi}_3\text{O}_8$) that removes glass forming elements from the glass matrix and would induce a decrease of its chemical durability is usually avoided (Kim *et al.*, 1995). Another issue related to crystallization could be the formation of cracks in the glass that can be due to the difference of thermal expansion coefficient between the crystals and the glass or to the incorporation of actinides in large size crystals (Chouard *et al.*, 2019). The melt viscosity must be around 10 Pa s both to enable a good melt homogenization (waste dissolution rate) and fining, to limit the evaporation of volatile elements and to enable melt casting in canisters. As classical soda-lime silica melts exhibit a viscosity close to 10^3 Pa s at 1100°C they are not suitable for waste vitrification in comparison with the borosilicate and aluminophosphate melts used in nuclear waste vitrification plants which are much less viscous. As waste composition variations may occur during industrial nuclear production, it is also necessary that the glass frit formula must be flexible enough to maintain acceptable wasteform properties (Vernaz *et al.*, 2012). To reach a final glass frit formulation, numerous laboratory scale and pilot unit tests using simulated inactive waste, followed by tests with radioactive waste in a hot laboratory are required (Jantzen, 2011; Vernaz *et al.*, 2012). In simulated inactive waste the radioactive elements (^{137}Cs , ^{90}Sr ...) can be replaced by stable natural isotopes (^{133}Cs , ^{88}Sr ...) whenever possible or using inactive surrogates exhibiting close chemical properties, for example, lanthanides to substitute actinides and rhenium to substitute technetium.

The first tentative use of glass as nuclear wasteform was investigated in Canada in the 1950s (Lutze, 1988), but the first industrial plant to produce borosilicate nuclear glasses only started in 1978 in France, using a metallic melter (Sombret, 1993).

Fig. 6 Scheme of the metallic melter used in France at the La Hague plant to immobilize commercial HLW in borosilicate glasses (glass production capacity $\sim 25 \text{ kg h}^{-1}$). In this two-step vitrification process, liquid waste solutions are firstly evaporated and calcined in a rotating furnace (in red). Melt stirring in the furnace enables the presence of significant amounts of insoluble noble metals by limiting the sedimentation risks. Modified from Vernaz, E., Gin, S., Veyer, C., 2012. Waste glass. In: Konings, R.J.M. (Ed.), *Comprehensive Nuclear Materials*, vol. 5. pp. 451–483. with permission from Elsevier.

Since this date, several industrial vitrification plants have been developed over the world to immobilize civilian or defense HLW using either ceramic or metallic melters (Ojovan and Lee, 2005; Jantzen *et al.*, 2011; Pegg, 2015; Donald, 2016). Metallic melters used in France and in the UK are made of refractory metallic Ni-Cr-rich alloys in which the melt is heated indirectly by induction from the furnace wall and HLW solutions are calcined before injection simultaneously with a glass frit into the furnace (Fig. 6) (Sombret, 1993; Harisson, 2014), while ceramic melters used for instance in the US, Russia, Japan and China are made of refractory ceramic blocks in which the melt is heated directly by the Joule effect by means of submerged electrodes whereas HLW can be injected as slurry directly into the furnace (Jantzen, 2011). A more recent alternative melting technique referred to as cold crucible induction process enabling the melt to be directly heated by induction is employed in particular in France and in Russia (Sobolev *et al.*, 2005; Vernaz *et al.*, 2012; Stefanovsky *et al.*, 2010).

Usually, in all cases, the melt must be as homogeneous as possible in the furnace in order to limit the problems that could be induced by the settling of particles (clogging, short-circuits) and to reduce the presence of heterogeneities in the glass. However, melt stirring allows melts to be processed with significant amounts of insoluble particles such as noble metals. The glass frit composition and waste loading are usually chosen to avoid, as much as possible, important crystallization and liquid-liquid phase separation during melting and cooling in canisters. Nevertheless, whatever the glass frit composition, the noble metals coming from HLW (Table 1) are almost insoluble in the melt (solubility $\sim 100 \text{ ppm}$) and are present as micrometric crystalline heterogeneities in glasses (RuO_2 , Pd, Rh, Pd-Te alloy) (Fig. 4). They represent only a very small fraction in the glass ($< 1 \text{ vol\%}$), but their presence in the melt increases its viscosity and affects its electrical conductivity (Pflieger *et al.*, 2009), and during cooling they may act as nucleation sites for heterogeneous crystallization (Pacaud *et al.*, 1991; Orlhac *et al.*, 1999; Chouard *et al.*, 2015). Classically, at laboratory scale or full-scale, tests are carried out on inactive compositions to evaluate the melt crystallization and phase separation tendency by studying the nature and the amounts of crystals or separated phases formed either after casting (to check melt homogeneity) or after isothermal treatments between the melting temperature and the glass transition temperature (T_g), or after controlled cooling from the melt (Orlhac *et al.*, 1999; Rose *et al.*, 2011; Chouard *et al.*, 2016) (Fig. 7).

In order to avoid any risk of crystallization during the interim storage and geological disposal, the glass temperature in canisters (due to radioactivity) must always remain lower than T_g , where atomic diffusion is very weak. This limits waste loading or involves adapting glass composition to increase T_g . For instance, for the French R7T7 borosilicate nuclear glass with $T_g \sim 510^\circ\text{C}$, the equilibrium temperature reached in glass bulk one day after melt casting in canisters is about 400°C (i.e., about 100°C below T_g) and then very slowly decreases (Fig. 8). The experimental crystallization studies and long-term simulations performed on this glass confirmed that the main crystalline phases (CaMoO_4 , ZnCr_2O_4 , CeO_2) that may form could only grow at the beginning of melt cooling above T_g (Fig. 8). For instance, it was estimated by simulation that the time required to reach the total crystallization of CeO_2 and ZnCr_2O_4 phases in this glass (without considering the presence of platinoid heterogeneities) would be respectively 10^{28} and 57.10^3 years at 690°C (i.e., well above T_g) (Orlhac, 1999).

Thermal stability of $\text{SiO}_2\text{-B}_2\text{O}_3\text{-Al}_2\text{O}_3\text{-Na}_2\text{O-CaO}$ glasses with high Nd_2O_3 and MoO_3 concentrations. *J. Alloy. Compd.* 671, 84–99, with permission from Elsevier.

Fig. 8 Model of the changes of the crystallized fraction (in vol%) of ZnCr_2O_4 (red) and CeO_2 (green) formed during cooling in the bulk of the R7T7 glass as a function of the time after melt casting in canister, following the bulk thermal change shown in the inset (natural cooling of a 400 kg cylindrical glass block). The crystallized fractions were calculated from the nucleation and crystal growth rates of the two phases versus temperature. It appears that a very weak crystallization is only expected at the beginning of melt cooling. Based on Orhac, X., 1999. Study of the Thermal Stability of Nuclear Glass. Long-Term Evolution Modeling (Ph.D. thesis). France: University of Montpellier II. (In French) Available at: http://www.iaea.org/inis/collection/NCLCollectionStore/_Public/31/058/31058405.pdf.

Nuclear Glasses Structure and Waste Incorporation

Even if numerous works have been performed on various kinds of glass compositions, such as iron phosphate and lead iron phosphates (Sales and Boatner, 1986; Jantzen, 2011; Bohre *et al.*, 2017), and lanthanide borosilicates (Meaker *et al.*, 1996;

Table 2 Average composition of the French R7T7 nuclear borosilicate glass produced to immobilize HLW originating from the reprocessing of ^{235}U enriched UO_2 spent nuclear fuel with a waste loading of about 17 wt%. Fines suspension correspond to metallic particles present in HLW solutions generated during the fuel shearing operation. The inactive version of this glass, used for laboratory experiments, is referred to as SON68 glass

Oxide	wt%
SiO_2	45.6
B_2O_3	14.1
Na_2O	9.9
Al_2O_3	4.7
CaO	4.0
Fe_2O_3	1.1
$\text{NiO} + \text{Cr}_2\text{O}_3$	0.2
Li_2O	2.0
ZnO	2.5
P_2O_5	0.2
(FP + Zr) oxides + fines suspension	16.4
actinide oxides	0.6

Note: Vernaz, E., Gin, S., Veyer, C., 2012. Waste glass. In: Konings, R.J.M. (Ed.), *Comprehensive Nuclear Materials*, vol. 5. Elsevier Science, pp. 451–483.

Jantzen, 2011) to immobilize HLW, borosilicate glasses remain with aluminophosphate glasses (belonging to the P_2O_5 - Al_2O_3 - Na_2O system) the only kinds of glassy wasteforms produced industrially for HLW immobilization. However, because of their inferior chemical durability in aqueous environment and thermal stability, and the fact that their melts are more corrosive than borosilicate melts, aluminophosphate glasses are less used than borosilicate glasses (Bohre *et al.*, 2017). Nevertheless, aluminophosphate glasses can incorporate more easily in their structure higher amounts of molybdenum, actinides, lanthanides, sulfates and halides and thus appear more adapted than borosilicate glasses to incorporate for instance Russian waste with high content of Al, Mo and sulfates (Laverov *et al.*, 2016).

To illustrate the chemical complexity of nuclear glasses used to immobilize HLW, the composition of the French R7T7 borosilicate nuclear glass is given in Table 2 and Fig. 9 where SiO_2 , B_2O_3 , Al_2O_3 , Na_2O , Li_2O , CaO and ZnO come from the glass frit and the other compounds from HLW solutions (Fig. 3). In order to study at laboratory scale the structure, the thermal stability and the long-term behavior (chemical durability and self-irradiation effects) of such very complex borosilicate glasses, researchers preferentially used simplified and inactive compositions, such as the International Simple Glass (ISG) as reference glass which is a 6-oxide glass (SiO_2 , B_2O_3 , Al_2O_3 , Na_2O , CaO , ZrO_2) considered as a good analog of the R7T7 glass (Kaspar *et al.*, 2019).

In such borosilicate nuclear glass compositions, the amount of SiO_2 (< 50 wt%) is significantly lower than in commercial soda-lime silicate glasses such as flat glass (> 70 wt%) and the presence of significant amounts of alkali oxides and B_2O_3 (close to 30 wt% in the R7T7 glass) enable them to be melted and cast at relatively low temperature (1100–1150°C) in comparison with soda-lime silicate glasses (~1400–1500°C) because of the well-known fluxing and fluidizing effect of B_2O_3 and alkali oxides. Moreover, to limit the risks of matrix demixing during melt cooling, the relative proportions of SiO_2 , B_2O_3 and alkali oxides are chosen outside the phase separation region in the ternary SiO_2 - B_2O_3 -(Na_2O , Li_2O) phase diagrams (Jantzen, 1986). Nevertheless, in order to maintain a good chemical durability against water alteration the proportion of B_2O_3 + alkali oxides must not be too high. As in borosilicate nuclear glasses there is generally an excess of alkali and alkaline-earth oxides compared to Al_2O_3 (such glasses are called peralkaline glasses), the glassy network is constituted of interconnected SiO_4 , BO_4^- , BO_3 and AlO_4^- units with alkali and alkaline-earth cations charge compensating the BO_4^- and AlO_4^- units (Fig. 10), AlO_4^- units being preferentially charge compensated by alkali cations (Caurant *et al.*, 2008). The excess of alkali and alkaline-earth oxides of the glass frit forms NBOs on SiO_4 tetrahedra which enables the majority of the wide spectrum of fission products and actinides that are present as cationic M^{n+} species in the waste to be incorporated, forming more or less strong M–O–Si bonds (see the Nd–O–Si bonds in Fig. 1). These alkali and alkaline-earth cations are not dispersed homogeneously in the glass structure but tend to form percolation channels in NBO-rich regions (depolymerized regions in Fig. 1) (Le Losq *et al.*, 2017) in which can be incorporated M^{n+} cations.

In comparison with cationic species, anionic species such as halide (F^- , Cl^- , I^-) and sulfur (S^{2-}) that may be present in several kinds of HLW are hardly soluble in borosilicate glasses because of the difficulty to connect them efficiently to the borosilicate network and their high tendency to volatilize during melting (Gin *et al.*, 2017b). The facility to dissolve M^{n+} cations in a borosilicate glass structure depends on both their size and charge. Generally, the higher their cationic field strength F_s , the higher their tendency to impose their local environment with strong M–O bonds with the oxygen anions available in the glass structure and the lower their solubility due to an increasing phase separation or crystallization tendency (the field strength of a cation in an oxide can be defined as $F_s = Z/d^2$ where Z is the cation charge and d is the mean cation-oxygen distance). When M^{n+} cations are linked to the borosilicate network, they form MO_n polyhedra with BOs or/and NBOs and their preference to connect to NBOs increases with F_s . For instance, lanthanide Ln^{3+} cations are preferentially connected to NBOs whereas alkali cations have both

Fig. 9 Relative abundance (wt%) of the different families of elements present in the R7T7 nuclear glass composition.

Fig. 10 (a) Snapshot of a 6-oxides borosilicate glass structure with composition close to that of the ISG glass from molecular dynamics simulations showing the interconnection between SiO_4 (yellow), BO_3 and BO_4 (green), AlO_4 (pink) and ZrO_6 (blue) polyhedra. The purple and green crosses represent respectively sodium and calcium cations. (b) Occurrence probability of different connections between SiO_4 , BO_x ($x = 3$ or 4) and AlO_x ($x = 4$ (98%) and $x = 3$ or 5 (2%)) polyhedra in a 4-oxides borosilicate glass ($\text{SiO}_2\text{-B}_2\text{O}_3\text{-Al}_2\text{O}_3\text{-Na}_2\text{O}$) derived from the ISG glass by converting CaO to Na_2O and ZrO_2 to SiO_2 under the same mole percentage. Molecular dynamics simulation results (blue) are compared to theoretical values by assuming a random distribution of network former atoms (red): the similarity of the results shows that the network former atoms tend to be randomly distributed. Reproduced from Lu, X., Deng, L., Kerisit, S., Du, J., 2018. Structural role of ZrO_2 and its impact on properties of borosilicate nuclear waste glasses. NPJ Mater. Degrad. 2, 19, with permission from Springer Nature. Ren, M., Deng, L., Du, J., 2017. Bulk, surface structures and properties of sodium borosilicate and borosilicate nuclear waste glasses from molecular dynamics simulations. J. Non Cryst. Solids 476, 87–94, with permission from Elsevier.

NBOs and BOs in their coordination sphere (Du and Cormack, 2005). The lowest F_s cations such as alkalis and alkaline-earths insure local charge compensation around MO_n polyhedra and complete the bond valence of the oxygen atoms engaged in M–O–Si bonds (see the example of NdO_n polyhedra charge compensated by Na^+ and Ca^{2+} cations in Fig. 1); these cations are thus essential to facilitate the dissolution of M^{n+} cations in the glassy network (formation of NBOs + charge compensation of MO_n polyhedra), and they strongly contribute to its structural flexibility. Nevertheless, peraluminous borosilicate glass compositions defined by an excess of Al^{3+} cations in comparison with the amount of alkali and alkaline-earth cations have also been envisaged as potential wasteforms with enhanced physical and chemical properties in comparison with peralkaline borosilicate glasses because of the possibility of high F_s elements present in HLW such as lanthanides to act as charge compensators of AlO_4^- units (Gasnier *et al.*, 2014; Piovesan *et al.*, 2018).

Let us now consider successively the incorporation in the structure of nuclear borosilicate glasses of several families of elements present in HLW.

Incorporation of Alkalis and Alkaline-Earths

The alkali and alkaline-earth cations that may be present in HLW (Cs^+ , Rb^+ , Mg^{2+} , Ba^{2+} , Sr^{2+}) play the same role of modifier or charge compensator as the alkali and alkaline-earth cations brought by the glass frit, and so they are thus generally easily dissolved in the glass structure. Nevertheless, depending on waste composition, they may partly separate and crystallize with anionic entities poorly soluble in the melt and in the glass such as orthophosphate (PO_4^{3-}) and molybdate (MoO_4^{2-})

polyanions (Fig. 4), also coming from the waste but that are not connected to the borosilicate network (obviously the alkali and alkaline-earth cations Na^+ , Li^+ and Ca^{2+} brought by the glass frit may also separate with these anionic entities). Such separation can be a problem if for instance the long-lived ^{137}Cs isotope crystallizes in poorly durable phases such as alkali molybdates because Cs^+ has a high mobility in the geological environment. Nevertheless, the crystallization of such alkali-rich phases may also lead to an increase of the overall wasteform durability if they do not percolate through the surrounding glass (see below, the case of molybdenum) (Nicoleau *et al.*, 2015).

Incorporation of Transition Metals

Numerous transition metals are present in HLW, originating either from nuclear fuel fission (Tc, Mo, Zr...), from reprocessing equipment (Fe, Ni, Cr) or from metallic cladding (Zr). Some of these metals can be particularly problematic during the vitrification process or for the long-term properties of the wasteforms because they can be highly volatile, such as Tc (for which all isotopes are radioactive) or may exhibit low solubility in the melt and during cooling because of their high tendency to phase separate (Mo) and/or to crystallize (Cr) which limits the waste loading, if wasteforms without crystals are to be obtained.

The case of technetium

As Tc^{7+} is very volatile during melting (it is present as very mobile TcO_4^- anions not connected to the borosilicate network), it is important to try to increase its retention by operating under more reducing conditions in order to promote Tc^{4+} that is less volatile, probably because it is present as less mobile TcO_6 octahedral units connected to the borosilicate network (Muller *et al.*, 2014). About 0.4 wt% TcO_2 is present in the R7T7 glass. In laboratory scale experiments, rhenium that belongs to the same column of the periodic table as Tc, is frequently used as a non-radioactive surrogate for Tc (Goel *et al.*, 2013).

The case of chromium

Chromium is poorly soluble in borosilicate melts and the R7T7 glass contains about 0.5 wt% Cr_2O_3 . It is non-radioactive and only comes from the reprocessing and vitrification process (tank and metallic melter corrosion). It is mainly present as Cr^{3+} (mixed with Cr^{6+} whose proportion depends on the redox melting conditions) in borosilicate glasses with a strong stabilization in an octahedral CrO_6 environment. This may explain the high crystallization tendency of Cr_2O_3 or spinel phases such as ZnCr_2O_4 in the presence of spinel-forming components such as ZnO (Fig. 8) which may lead to deleterious effects on melter performance (Hrma *et al.*, 2006).

The case of zirconium

Zirconium is both a fission product (with about 20% ^{93}Zr , a long-lived isotope with half-life of 1.5 million years) and an additional element coming from the fuel metallic cladding (zircalloy). It can also be present in the glass frit added to the waste to improve glass durability. The R7T7 glass contains about 2.7 wt% ZrO_2 . Zirconium only occurs as Zr^{4+} in borosilicate glasses and is preferentially located in octahedral ZrO_6 sites connected to the silicate network by strong Zr-O-Si bonds, but Zr-O-B may also exist (Galoisy *et al.*, 1999; Lu *et al.*, 2018) (Fig. 10). Alkali and alkaline-earth cations insure local electroneutrality and complete the bond valences of oxygen atoms surrounding zirconium that thus acts as a reticulating agent because it induces a decrease of the proportion of NBOs. As a consequence, the addition of ZrO_2 to the glass leads to a significant increase of T_g . Moreover, ZrO_6 units would be preferentially charge compensated rather than the BO_4 units (Angeli *et al.*, 2008). Consequently, in spite of its high F_s , Zr^{4+} is usually rather well incorporated in the network of nuclear borosilicate glasses if there are enough charge compensators available. Nevertheless, the crystallization of Zr-rich phases such as ZrO_2 and ZrSiO_4 can occur for particular borosilicate glass compositions, but these phases are well-known for their high chemical durability (Chen *et al.*, 2020). Moreover, it has been shown that ZrO_2 addition to borosilicate glasses induces a decrease of the initial dissolution rate in water but leads to a greater degree of alteration for longer times (Caillateau *et al.*, 2008) which can be explained by the local strengthening of the glass network in the Zr neighborhood due to the strong Zr-O-Si bonds. Finally all zirconium remains in the alteration layer on the glass surface (Angeli *et al.*, 2008).

The case of molybdenum

Molybdenum is a rather abundant stable fission product present in HLW solutions (Fig. 3) that mainly occurs as Mo^{6+} in nuclear borosilicate glasses prepared in oxidizing conditions. Due to its high F_s , Mo^{6+} occurs as isolated and mobile molybdate (MoO_4^{2-}) tetrahedral entities in the depolymerized regions of the structure rich in alkali and alkaline-earth cations (Fig. 11). Indeed, Mo-O-Si bonds between Mo and the glassy network cannot exist according to bond valence considerations because in such a situation the oxygen atom connecting Mo and Si would be overbonded (Calas *et al.*, 2003).

Similarly to other highly charged (+5, +6, +7) elements present as isolated oxoanionic species in borosilicate glasses (PO_4^{3-} , CrO_4^{2-} , TcO_4^-), Mo is thus poorly soluble in the structure of borosilicate glasses (solubility $\sim 1\text{--}3$ mol% MoO_3) and has a high tendency to phase separate during melting and cooling, and then to crystallize as alkali and alkaline-earth molybdates (Fig. 12). For instance, during the vitrification process, the presence of important amounts of molybdenum in the waste can lead to the formation of a Mo-rich phase called "yellow phase" that separates from the glass melt during vitrification and is undesirable

Fig. 11 Structural scheme showing the way molybdenum may enter in borosilicate nuclear glasses as isolated MoO_4^{2-} entities located in the depolymerized regions (DR) of the glassy network rich in non-bridging oxygen atoms (NBOs) and alkali + alkaline-earth cations (here Na^+ and Ca^{2+}). Polymerized regions (PR) rich in bridging oxygen atoms (BOs) are also shown.

Fig. 12 Schematic showing the microstructural changes during melt cooling of a Mo-rich soda-lime borosilicate glass showing 4 steps: (1) homogeneous melt M during melting ($T > 1100^\circ\text{C}$), (2) liquid-liquid phase separation ($M_1 + M_2$) during cooling forming droplets M_2 , (3) CaMoO_4 crystallization ($T \leq 900^\circ\text{C}$) and (4) Na_2MoO_4 crystallization ($T \leq 650^\circ\text{C}$) in the droplets M_2 . Based on Magnin, M., 2009. Study of Phase Separation and Crystallization Phenomena in Soda-lime Borosilicate Glass Enriched in MoO_3 . (Ph.D. thesis). Paris: University Pierre and Marie Curie. Available at: https://inis.iaea.org/collection/NCLCollectionStore/_Public/42/039/42039802.pdf.

both for melter operations and wasteform properties which limits waste loading (McKeown *et al.*, 2017). The situation is different for phosphate glasses where Mo^{6+} can be connected to the phosphate network through $\text{Mo}-\text{O}-\text{P}$ bonds with a high fraction of MoO_6 entities, which explains the higher MoO_3 solubility in this kind of glass (Santagneli *et al.*, 2007). For instance, up to 83 mol % MoO_3 can be dissolved in pure P_2O_5 glass (Bridge and Patel, 1986).

As alkaline-earth molybdates such as CaMoO_4 (powellite) are much less soluble in water than alkali molybdates, that may also incorporate radioactive Cs, if crystallization cannot be avoided – as in Mo-rich waste (Fig. 4) – it is strongly preferable to orientate

Fig. 13 (a) Changes in XRD patterns with B₂O₃ content of slowly cooled soda-lime borosilicate glasses containing about 2.5 mol% MoO₃ showing the increasing CaMoO₄ (C) crystallization tendency at the expense of Na₂MoO₄ (N_α) when the B₂O₃ content increases. (b) Changes with B₂O₃ content of ⁹⁵Mo MAS NMR spectra of quenched soda-lime borosilicate glasses containing about 2.5 mol% MoO₃ compared with spectra of reference glasses of the SiO₂-CaO-MoO₃ (SiCaMo) and SiO₂-Na₂O-MoO₃ (SiNaMo) systems showing the progressive Ca-enrichment in the environment of MoO₄²⁻ entities when the B₂O₃ content increases. Modified from Magnin, M., Schuller, S., Mercier, C., *et al.*, 2011. Modification of molybdenum structural environment in borosilicate glasses with increasing content of boron and calcium oxide by ⁹⁵Mo MAS NMR. *J. Am. Ceram. Soc.* 94, 4274–4282, permission from John Wiley and Sons.

crystallization towards alkaline-earth molybdates. This can be performed for instance by increasing the B₂O₃ content in Mo-rich borosilicate glasses. As BO₄⁻ units are preferentially charge compensated by alkalis, their presence in the glassy network (Fig. 1) induces an increase of the proportion of alkaline-earth cations in the region surrounding MoO₄⁻ entities which promotes the crystallization of alkaline-earth molybdates at the expense of alkali molybdates (Caurant *et al.*, 2007b; Magnin *et al.*, 2011) (Figs. 12 and 13).

The presence in HLW or the addition to the melt of certain elements such as lanthanides and vanadium can help the incorporation of molybdenum in borosilicate melts and glasses. For instance, it has been shown that the progressive addition of Nd₂O₃ to a Mo-rich borosilicate glass enables molybdate crystallization to be suppressed during melt cooling (Chouard *et al.*, 2011). This beneficial effect of lanthanides on molybdenum solubility has also been found for other lanthanides of various sizes (La, Ce, Sm, Er, Yb) (Patil *et al.*, 2018). Two alternative structural models have been proposed to explain this effect of lanthanides, all considering that Ln³⁺ and MoO₄²⁻ ions are located in the same regions of the glass structure (Chouard *et al.*, 2011; Brehault *et al.*, 2018). As lanthanides are already present in significant concentration in HLW (Fig. 3), their presence may participate in molybdenum stabilization in nuclear borosilicate glasses. It has also been reported that the addition of vanadium as V₂O₅ in Mo-rich borosilicate glasses would help to stabilize MoO₄²⁻ and to avoid yellow phase formation; the presence of VO₄³⁻ tetrahedral units sharing alkali cations with MoO₄²⁻ would be responsible for this effect (McKeown *et al.*, 2017). Recent studies also indicate that the addition of P₂O₅ to Mo-rich borosilicate glasses would help MoO₃ dissolution in the melt, probably by forming phosphorus-rich regions able to incorporate molybdenum (Prakash *et al.*, 2019; Krishnamurthy *et al.*, 2020). Magnesium aluminosilicate glass compositions have also been reported to incorporate more molybdenum than borosilicate glasses (Tan *et al.*, 2015). It is interesting to note that in spite of their low durability, the separation or/and crystallization of alkali molybdates in borosilicate glasses does not necessarily imply a decrease of the chemical durability in water of the overall wastefrom. For example, the separation of isolated (i.e., non-percolating) sodium molybdate particles in a borosilicate glass may lead to an increase of the surrounding glass durability (due to Na₂O depletion and decrease of the proportion of NBOs) which controls the alteration of the poorly durable sodium molybdate particles dispersed in the glass (Fig. 14) (Nicoleau *et al.*, 2015).

Fig. 14 (a) Evolution with time of the normalized mass loss for boron during alteration at 90°C in water of a sodium borosilicate glass with increasing MoO₃ contents (0–10 mol%) showing an important decrease of the amount of glass altered. Above 1.4 mol% MoO₃ glasses were heterogeneous (phase separation + Na₂MoO₄ crystallization). (b) Evolution of the initial dissolution rate r_0 for Si for the same glass series as a function of the percentage of NBOs (that decreases with MoO₃ content). A clear correlation is observed between the decrease of r_0 of the glassy phase (where Si is located) and the drop in the number of NBOs (increase of the polymerization of the glassy network). Modified from Nicoleau, E., Schuller, S., Angeli, F., *et al.*, 2015. Phase separation and crystallization effects on the structure and durability of molybdenum borosilicate glass. *J. Non Cryst. Solids* 427, 120–133, p. 130 permission from Elsevier.

Incorporation of Lanthanides and Actinides

Lanthanides (Ln) with yttrium represent one of the most abundant family of FP in HLW (**Fig. 3**) where the four largest Ln (La, Ce, Pr, Nd) represent more than 90 wt% of all Ln. Only a small fraction of lanthanides is radioactive (the longest-lived Ln isotope is ¹⁵¹Sm with half-life of 93 years and low concentration) and all Ln are poorly soluble in water. Due to their 4fⁿ electronic configuration with deep 4f level, lanthanides mainly occur at oxidation state +III, except Ce that frequently exists as Ce³⁺ and Ce⁴⁺ depending on redox conditions. In comparison, the amount of actinides (An) in HLW is much smaller than that of lanthanides (**Fig. 3**) but they are all radioactive (α -radionuclides). They mainly consist of minor actinides (Np, Am, Cm) and small amounts of U and Pu. Because of their 5fⁿ electronic configuration, U, Np and Pu may occur at higher oxidation state than +III, but as the energy and the spatial extension of the 5f orbital drops rapidly with increasing actinides atomic number, heavier actinides (Am, Cm) behave more as lanthanides and only exist as Am³⁺ and Cm³⁺ in glasses (Eller *et al.*, 1985). This is the reason why Ln³⁺ (such as Nd³⁺) with close ionic radius to Am³⁺ and Cm³⁺ are frequently used as Am and Cm non-radioactive surrogates in laboratory experiments on nuclear glasses. It has also been shown that in borosilicate glasses Nd³⁺ and Am³⁺ behave similarly during crystallization (Bardez-Giboire *et al.*, 2017).

The case of lanthanides

Despite their high F_s Ln³⁺ cations are usually well dissolved in nuclear borosilicate glasses. Nevertheless, for high waste loading the crystallization of Ln-rich phases may be observed during melt cooling such as Ca₂Ln₈(SiO₄)₆O₂ (apatite) (**Fig. 7**), and Ln borates and borosilicates depending on glass composition (Quintas *et al.*, 2008; Chen *et al.*, 2020). Moreover, the size of Ln³⁺ cations may strongly impact the nature of RE-rich crystals and glass crystallization tendency (Loiseau *et al.*, 2004; Quintas *et al.*, 2008; Kidari *et al.*, 2012; Chen *et al.*, 2020). Even if a phase like Ca₂Ln₈(SiO₄)₆O₂ exhibits a good chemical durability, it tends to become amorphous and swell under self-irradiation due to the α -decay of MA that can partly substitute for Ln in crystal structures (Weber, 1983). This could then induce local strains and cracks in the surrounding glass (Weber *et al.*, 1979) depending on crystal size which would be problematic for the long-term behavior of wasteforms; this requires control of their crystallization and particularly their size or to avoid Ln-rich phase formation, modifying for instance glass composition to improve Ln³⁺ solubility (Chouard *et al.*, 2019). Moreover, it has been reported that the crystallization of Ca₂Ln₈(SiO₄)₆O₂ in borosilicate glasses tends to make them less durable against water alteration because of the changes of both the composition (CaO and Ln₂O₃ depletion), the structure and the durability of the surrounding glass in comparison with a homogeneous glass (Nicoleau *et al.*, 2016). Nevertheless, glass-ceramics containing Ca₂Ln₈(SiO₄)₆O₂ or NaLn₉(SiO₄)₆O₂ crystals have been proposed as wasteform for actinides immobilization because of the capacity of apatite crystals to incorporate trivalent actinides in their structure (Caurant *et al.*, 2006; Zhao *et al.*, 2001).

Ln₂O₃ is very weakly soluble in pure silica glass (strong phase separation tendency) due to the high F_s of Ln³⁺ ions that do not succeed to satisfy their environment because of the insufficient quantity of NBOs, and thus rapidly tend to form clusters. The addition of alkali and alkaline-earth oxides enables its solubility to significantly increase both by creating numerous NBOs and by bringing alkali and alkaline-earth cations that may ensure local charge compensation in the region surrounding LnO_n polyhedra as shown in **Fig. 1**. When added to silicate or borosilicate glasses, Ln₂O₃ usually act as modifier oxide forming NBOs (**Fig. 15**) and Ln³⁺ are linked to NBOs forming strong Ln–O–Si bonds which explains the rise of T_g with Ln₂O₃ content (Schaller *et al.*, 1999; Kidari *et al.*, 2012; Gaddam *et al.*, 2019). Moreover, the impact of La₂O₃ content on the alteration kinetics of borosilicate glasses shows that lanthanum improves their chemical durability in water and La³⁺ ions (as other Ln) are almost integrally retained in the alteration layer on the glass surface (Molières *et al.*, 2013; Ménard *et al.*, 1998).

Fig. 15 Changes in ^{29}Si MAS NMR spectra when increasing amounts of La_2O_3 (0–10 mol%) are added to $75\text{SiO}_2\text{-}25\text{Na}_2\text{O}$ glass showing evidence of the depolymerization of the silicate network and the modifier role of La_2O_3 (Q^n represents SiO_4 tetrahedral units with n BOs). Reproduced from Schaller, T., Stebbins, J.F., Wilding, M.C., 1999. Cation clustering and formation of free oxide ions in sodium and potassium lanthanum silicate glasses: Nuclear magnetic resonance and Raman spectroscopic findings. *J. Non Cryst. Solids* 243, 146–157, with permission from Elsevier.

Fig. 16 Evolution with the Nd_2O_3 content in a borosilicate glass ($64\text{SiO}_2\text{-}9.3\text{B}_2\text{O}_3\text{-}3.2\text{Al}_2\text{O}_3\text{-}15\text{Na}_2\text{O}\text{-}6.5\text{CaO}\text{-}2\text{ZrO}_2$ mol%): (in red) of the amount of $\text{Na}_2\text{O} + \text{CaO}$ needed to compensate the negative charge excess of NdO_7 polyhedra (see Fig. 1) in the glass structure (4 moles ($\text{Na}_2\text{O} + \text{CaO}$) for 1 mole Nd_2O_3); (in green) of the amount of $\text{Na}_2\text{O} + \text{CaO}$ available both to charge compensate NdO_7 polyhedra and to supply NBOs for their formation, taking into account the amount of charge compensators used for the compensation of AlO_4^- and BO_4^- units deduced from NMR results. Above about 3 mol% Nd_2O_3 (vertical dotted green line) there is not enough NBOs and charge compensators available to enable the incorporation of Nd^{3+} as isolated NdO_7 entities which thus rapidly tend to agglomerate and to separate or crystallize as $\text{Ca}_2\text{Nd}_8(\text{SiO}_4)_6\text{O}_2$ phase (apatite) when the charge compensators deficiency increases (red arrow). The pictures of slowly cooled samples (6°C min^{-1}) from the melt with increasing Nd_2O_3 content show their strong crystallization tendency when the amount of $\text{Na}_2\text{O} + \text{CaO}$ becomes insufficient.

To be stabilized and uniformly dispersed in a glass structure, Ln^{3+} needs to satisfy easily its environment finding enough alkali or alkaline-earth cations and NBOs (Angeli et al., 2013). When adding increasing amounts of Ln_2O_3 to glass, Ln^{3+} remains soluble in the glass network as long as there are enough charge compensators, but beyond this concentration limit the separation or crystallization of a Ln-rich phase can be observed (Fig. 16).

Fig. 17 Changes in the Fourier transforms of the Nd L_{III} -edge EXAFS spectra of neodymium in a borosilicate glass (61.8SiO₂-9B₂O₃-16.5Na₂O-7.2CaO-2ZrO₂-3.5Nd₂O₃ mol.%) to which increasing amounts of Al₂O₃ (0–15.5 mol%) were progressively substituted for Na₂O + CaO, keeping all other concentrations constant. All compositions were peralkaline except that with 15.5 mol% Al₂O₃ was peraluminous and for which there is evidence for the presence of Al as second neighbor of Nd (Nd³⁺ acts as charge compensator of AlO₄[−] units inducing a decrease of the second neighbor distance). The images given at the bottom of the curves show the changes in the aspect of the glasses after cooling from the melt at 6°C min^{−1}. No crystals were observed with 0 and 3 mol% Al₂O₃, but crystals (Ca₂Nd₆(SiO₄)₆O₂) and phase separation (100 nm Nd-rich droplets) were detected respectively with 6 and 12 mol% Al₂O₃ because of the decreasing amount of Na₂O + CaO available to enable dissolution of Nd³⁺ ions. However, when the glass became peraluminous (15.5 mol% Al₂O₃), Nd³⁺ ions were again dispersed in the glass structure. Based on Bardez, I., 2004. Study of the Structural Characteristics and Properties of Glasses Rich in Rare Earths Intended for the Immobilization of Fission Products and Long-lived Elements. (Ph.D. thesis). Paris: University Pierre and Marie Curie. (in French). Available at: <https://pastel.archives-ouvertes.fr/pastel-00001075>.

Al₂O₃ content also has an important effect on the stabilization of Ln³⁺ in borosilicate glasses. For instance, the addition of increasing amounts of Al₂O₃ to a peralkaline borosilicate glass progressively destabilizes Ln³⁺ because aluminum (mainly present as AlO₄[−] units) is charge compensated in priority compared to LnO_n polyhedra which induces a progressive depletion of charge compensators available for lanthanides, and the separation or crystallization tendency of Ln-rich phases increases. However, when the composition becomes peraluminous (i.e., when there is not enough alkali and alkaline-earth cations to compensate all AlO₄[−] units), the solubility of Ln₂O₃ begins to increase because an increasing number of Nd³⁺ act as charge compensators for the excess AlO₄[−] units (Fig. 17), increasing their dispersion and thus their solubility in the glass structure. Such peraluminous borosilicate glasses have been envisaged to immobilize waste with high Ln₂O₃ contents because of their ability to incorporate higher quantities of Ln₂O₃ than peralkaline glasses and they exhibit higher chemical durability (Gasnier *et al.*, 2014; Piovesan *et al.*, 2018).

The case of actinides

While the chemical properties and the behavior of Am and Cm in borosilicate glasses appear close to that of trivalent lanthanides such as Nd (oxidation state +III, similar size, deep 4f and 5f levels) that can be used as Am or Cm surrogates, this is not the case for lighter actinides U, Np and Pu. Indeed, these three actinides may exist in different oxidation states (U⁴⁺, U⁵⁺, U⁶⁺, Np³⁺, Np⁴⁺, Np⁵⁺, Pu³⁺, Pu⁴⁺) depending on the conditions of glass preparation (temperature and redox). Plutonium mainly occurs as Pu⁴⁺ ions in nuclear glasses prepared under neutral or oxidizing conditions and it is only under strongly reducing conditions that almost all Pu⁴⁺ ions can be reduced to Pu³⁺ ions (Cachia *et al.*, 2006; Deschanel *et al.*, 2007). Neptunium exists as Np³⁺ only in glasses melted under strongly reducing conditions and mainly as Np⁴⁺ + Np⁵⁺ in glasses melted under more oxidizing conditions, whereas uranium is present as U⁴⁺ in glasses melted under reducing conditions and as both U⁵⁺ and U⁶⁺ if glasses are melted in oxidizing conditions (Gin *et al.*, 2017b). Because of their lower F_o, trivalent actinides (Pu³⁺, Am³⁺, Cm³⁺) are generally more soluble in glasses than actinides with higher oxidation states. This is true for plutonium whose solubility of Pu³⁺ is significantly higher than that of Pu⁴⁺. For instance, Pu solubility can be increased from 2.5 (melting in air without reducing agent)

Fig. 18 Structural scheme showing the way UO_2^{2+} (uranyl) entities could be incorporated in the depolymerized regions of a borosilicate glass. Reproduced from Connelly, A.J., Hyatt, N.C., Travis, K.P., *et al.*, 2013. The effect of uranium oxide additions on the structure of alkali borosilicate glasses. *J. Non Cryst. Solids* 378, 282–289, with permission from Elsevier.

to more than 4 wt% PuO_2 (melting in Ar with reducing agent) in a borosilicate glass (Cachia *et al.*, 2006). However, in the case of the highest uranium and neptunium oxidation states (U^{6+} , Np^{5+}) the situation is different because these elements would occur respectively as highly covalent linear uranyl (UO_2^{2+}) and neptunyl (NpO_2^{2+}) entities (Gin *et al.*, 2017b). These entities would be more soluble than the lower oxidation states of U and Np because of their easy dissolution in the depolymerized regions of the borosilicate glass structure where they would be connected to the NBOs of the network and charge compensated by modifier cations as has been proposed for uranyl entities (Fig. 18) (Connelly *et al.*, 2013). Structural studies performed on Pu^{3+} and Cm^{3+} in borosilicate glasses showed that these species are well dispersed in the glass structure and are respectively located in 8- and 7-fold coordinated sites (Deschanel *et al.*, 2007). Concerning the immobilization of Pu-rich waste in glassy wasteforms, it has been shown that lanthanide borosilicate glasses containing more than 40 wt% Ln_2O_3 (La_2O_3 , Nd_2O_3 , Gd_2O_3) were able to incorporate up to about 10 wt% PuO_2 whereas borosilicate glasses may dissolve only up to about 2 wt% and are less durable (Shiryaev *et al.*, 2009). As lanthanides, due to their very low solubility in water, Am, Cm and Pu are almost totally retained in the alteration layer on the glass surface, while the retention of Np and U in this layer may be lower depending on their oxidation state in the aqueous medium (Gin *et al.*, 2017b; Ménard *et al.*, 1998).

Long-Term Behavior of Nuclear Glasses

As it is usually considered that HLW must be isolated from the biosphere at least until their radiotoxicity level will drop back to the radiotoxicity level of the initial uranium ore used to prepare the fuel (Fig. 2), glassy wasteforms must keep their containment properties for a very long time, at least several tens of thousands of years. For this, they must exhibit very good long-term behavior concerning both their resistance against the self-irradiation induced by the decay of the radionuclides incorporated into their structure and their resistance against alteration by water (liquid or vapor) that may be in contact with the glass during geological disposal.

Self-Irradiation Resistance of Nuclear Glasses

The presence of high quantities of α and β radioactive elements (FP + MA) in nuclear glasses will induce numerous atomic displacements during their storage and disposal (Table 3). Indeed, during the α -decay of actinides, the α -recoil nuclei (with 80–120 keV energy) lose their energy in elastic collisions with the nuclei of their neighborhood and the α -particles produced (helium nuclei with 4–5 MeV energy) deposit their energy mainly by ionization processes but also by elastic collisions at the end of their paths. For each α -decay about 2400 atomic displacements are induced in the glass structure by the emitted α -particle and the recoil of the new nucleus. For β -particles (electrons) and γ -radiation, the energy transfer is dominated by ionization and electronic excitation processes and the effects on glass structure are expected to be much weaker because of the very low number of atomic displacements. Nevertheless, due to the short half-life of abundant FP such ^{137}Cs and ^{90}Sr , β -decays are the main source of radioactivity and heat generation in the first 500 years, while after this period MA become the main source (Fig. 2).

Table 3 Characteristics of α , β and γ radiations in nuclear glasses due to fission products and minor actinides

Irradiation	Number of events after 10^4 years	Range	Number of atomic displacements per event
α -decay	10^9		
α -particle		$\sim 20 \mu\text{m}$	~ 400
recoil nuclei		30 nm	~ 2000
β -decay	$7 \cdot 10^{19}$	$\sim 1 \text{ mm}$	~ 1
γ	$2 \cdot 10^{19}$	$\sim 2 \text{ cm}$	$\ll 1$

Note: Gin, S., Jollivet, P., Tribet, M., Peugeot, S., Schuller, S., 2017b. Radionuclides containment in nuclear glasses: An overview. *Radiochim. Acta* 105, 927–959.

While in ceramics the accumulation of atomic displacements frequently leads to amorphization (destruction of the long-range order) and swelling (increase of the volume) (Weber *et al.*, 1998), the effect of self-irradiation on the structure and properties is expected to be weaker for nuclear glasses that are already amorphous. In order to evaluate the impact of irradiation damage on the structure and the physical and containment properties of nuclear glasses during storage and disposal, different kinds of accelerated tests are performed (Weber, 2014). For example, in order to simulate the effect of α -decays on glasses, samples can be prepared by incorporating short-lived actinides such as ^{238}Pu or ^{244}Cm (with half-lives of respectively 87 and 18 years) or external irradiation experiments with charged particles (heavy ions, α -particles) can be performed on inactive samples (Weber *et al.*, 1997). Molecular dynamics is also used to simulate the displacement cascades generated in borosilicate glasses by heavy nuclear projectiles which is very helpful to understand the structural effects of α -decays (Peugeot *et al.*, 2014). The effects of γ -irradiation can be simulated using radioactive external sources and β -irradiation can be simulated by external irradiation with electrons (Van de Graaff accelerator). Internal and external irradiation experiments simulating α -decays showed that for borosilicate glasses with compositions close to that of the R7T7 nuclear glass, the density only slightly decreases ($< 1\%$) (Fig. 19) and an improvement of mechanical properties is observed ($\sim 30\%$ hardness reduction and increased resistance to cracking) (Peugeot *et al.*, 2006, 2014).

The behavior in glass structure of helium atoms formed after α -decays and capture of 2 electrons by each α -particle and the consequences of their possible accumulation in the glass structure remain to be clearly evaluated. However, the amount of helium generated in nuclear glasses used for commercial HLW immobilization would be only around 0.1–1 at% after 10^6 years and the formation of bubbles of significant size ($> 10 \text{ nm}$) has not been observed at room temperature (Gin *et al.*, 2017b; Peugeot *et al.*, 2014). Studies have also been performed to evaluate the impact of α -decays on the chemical durability of glasses. Leaching tests have been carried out in water on externally irradiated or short-lived actinides-doped borosilicate glasses. Whereas studies performed on self-irradiated and externally irradiated borosilicate nuclear glasses previously concluded that α -activity has no significant impact on the glass alteration rate by water (Peugeot *et al.*, 2007), more recent works show non-negligible impact of radiation damage on their alteration rate (Tribet *et al.*, 2020), which may affect to some extent the containment properties during disposal over the very long-term. Moreover, the alteration rate in water tends to increase if irradiated glasses are previously altered by water in vapor phase, which is expected to occur for a long time during disposal before alteration with liquid water (Bates *et al.*, 1984; Majerus *et al.*, 2020).

The impact of transmutation of radioactive elements present in nuclear glasses is also important to consider. The transmutation of FP such as ^{137}Cs and ^{90}Sr are accompanied by important valence and ionic radius changes ($\text{Cs}^+ \rightarrow \text{Ba}^{2+}$ and $\text{Sr}^{2+} \rightarrow \text{Y}^{3+} \rightarrow \text{Zr}^{4+}$) that can be easily accommodated in the flexible structure of nuclear glasses that contain high amounts of NBOs and charge compensators. For MA, as decay products are also actinides, they are expected to be incorporated similarly in glass structure (Gin *et al.*, 2017b).

The effect of self-irradiation on the structure of the glassy network of borosilicate glasses has been examined by structural characterizations on irradiated samples. Concerning β -decays, external irradiation of borosilicate glasses by electrons showed the formation of paramagnetic defects (as evidenced by EPR, Electron Paramagnetic Resonance), changes in the polymerization of the glassy network and the formation of dissolved molecular oxygen (Malchukova *et al.*, 2009). However, the presence of transition metals such as chromium and iron may significantly diminish the amount of defects and the structural changes induced under β -irradiation. This effect can be attributed to the capacity of transition metals to change their state charge by electron trapping leading to stable valence states, but this would not suppress the defects produced by hole trapping (electron holes being generated in glasses during electron irradiation) (Malchukova *et al.*, 2009). Concerning α -decays, NMR investigations of ^{244}Cm doped ISG glass showed only small modifications of the local structure: a slight variation of the environment of AlO_4^- units and a weak decrease ($\sim 7\%$) of the proportion of BO_4^- units were observed (Fig. 20). The decrease of the proportion of BO_4^- units under α self-irradiation was explained by local melting plus rapid quenching effects in the glass structure due to α -recoils and α -particles (Charpentier *et al.*, 2016), similar to the well-known effect of the quenching rate on the $\text{BO}_4^- \leftrightarrow \text{BO}_3$ equilibrium in borosilicate glasses (Angeli *et al.*, 2018). Moreover, during their displacement in the glass structure, the energy loss of α -particles would partly repair the regions damaged by α -recoils as shown by sequential and simultaneous ion irradiations (Mir *et al.*, 2015). These structural modifications and the formation of other point defects and changes in ring size distribution under α -irradiation that have also been reported may explain why irradiated borosilicate glasses are more reactive with water than pristine glasses (Tribet *et al.*, 2020).

Fig. 19 Evolution versus the α -decay cumulative dose of the density of a borosilicate glass doped with ^{244}Cm . A cumulative dose of about $3 \cdot 10^{18} \alpha/\text{g}$ corresponds to several thousand years of storage of active nuclear borosilicate glasses. Reproduced from Peugeot, S., Cachia, J.-N., Jégou, C., *et al.*, 2006. Irradiation stability of R7T7-type borosilicate glass. *J. Nucl. Mater.* 354, 1–13, p. 7. with permission from Elsevier.

Fig. 20 Comparison between the ^{11}B MAS NMR spectra (9.4 T) of a damaged (in blue) and annealed (in red) ^{244}Cm doped (0.13 mol% Cm_2O_3) borosilicate ISG glass. The damaged glass has accumulated an α -decays dose of $4.4 \times 10^{18} \alpha \text{ g}^{-1}$ equivalent to 10^4 years of disposal and the annealed glass has accumulated an α -decays dose of $7 \times 10^{16} \alpha \text{ g}^{-1}$. Resistance of Nuclear Glasses Against Alteration in Aqueous Environment

As any material, glasses chemically react with their environment and degrade over a long period of time. As oxide materials, the main “corroding” agent of glasses is water, either in the vapor or in the liquid state. This chemical degradation is an issue to all glasses and glass applications, such as natural glasses, commercial glasses and glasses of the cultural heritage. In the case of nuclear waste glasses, the central question is that of the kinetics: at which rate will the glass degrade into the alteration products and release the radioactive nuclei? It is considered that once the glass has degraded, the radiotoxic elements are released from this first barrier, and then their containment relies on the other barriers (Vernaz *et al.*, 2012). The degradation by water, or aqueous alteration, is the only process leading to the breakdown of the containment properties, as the other evolving processes such as crystallization may occur over a considerably longer period of time (Fig. 8).

Water reacts with glass by (1) hydration and ionic exchange, and (2) hydrolysis (Grambow and Müller, 2001; Conradt, 2008). Glass hydration and ionic exchange do not modify the glass structure; they produce a “hydrated glass” bearing molecular water and Si-OH (silanol) groups in place of the Si-OM groups where M are cations exchangeable with H^+ , such as alkali and alkaline-earth ions:

Hydrolysis is the nucleophilic, or acid-base reaction of water with the M-O bonds that breaks these bonds and produces solvated M species (M is any element bound to oxygen). The multi-step hydrolysis of the M-O bonds that form the glass network (M = Si, Al, B...) leads to the destabilization and dissolution of the glass material:

Every hydrolysis reaction has an equilibrium constant $K_{\text{eq},M}(T)$ that controls the amount of element M to be dissolved at a given temperature T and at equilibrium. Every hydrolysis reaction also has a kinetic rate $R_{M,T}(t)$ that is the initial rate $R_{M,T,0}$ weighted by the affinity factor:

$$K_{\text{eq},M}(T) = \exp\left(-\frac{\Delta G_M^0(T)}{RT}\right) \quad (3)$$

$$R_{M,T}(t) = R_{M,T,0} \left(1 - \frac{Q_M(t)}{K_{\text{eq}}(T)}\right) \quad (4)$$

Where $Q_M(t)$ is the reaction product of the hydrolysis of M at time t and $R_{M,T,0}$ is the initial rate.

In multicomponent glasses such as nuclear glasses, all components have different solubilities, all varying differently with the pH. The dissolution is then generally non-congruent, producing an alteration layer at the interface between the pristine glass and the solution, which contains the most insoluble components. For instance, alkalis and boron pass into solution, while Zr, Al (charge-compensated by Ca) (Angeli *et al.*, 2001), Fe, La, Mg, Ca generally stay completely or partially in the silicate alteration gel (depending on the pH) (Molières *et al.*, 2013). Moreover, the material dissolution is irreversible because the reverse reactions cannot back-produce the starting glass. Because of its low solubility and structural role as main network former, the dissolution rate of the glass is considered to be limited by the dissolution rate of SiO_2 . The affinity term controlling the kinetics is then the equilibrium with SiO_2 as amorphous silica (or as cristobalite in some geochemical models).

An important experimental approach is to measure the glass dissolution kinetics in static conditions (representative of the deep disposal condition) in various conditions of T, S/V (S surface of exposed glass, V volume of the solution), pH and solution composition. The solution is sampled at regular intervals and analysed by ICP-OES. From the measured concentrations $C_i(t)$, the normalized leached fractions in every element i are calculated by:

$$\text{NL}_i(t) = \frac{C_i(t) \times V}{x_i \times m \times \Sigma} \quad (5)$$

Where V is the volume of the solution, x_i is the mass fraction of element i in the glass composition, m is the mass of glass powder engaged in the experiment and Σ is the specific surface of the glass powder (in $\text{m}^2 \text{g}^{-1}$). Then, $\text{NL}_i(t)$ is in $\text{g m}^{-2} \text{d}^{-1}$ and represents the amount of dissolved glass considering the amount of element i that has passed into solution. Because B is very rarely found in the alteration layer, it is considered as a good tracer of the dissolution and is used to calculate the glass leached fraction and follows the glass dissolution kinetics (Fig. 14). Following numerous experimental studies (Caillateau *et al.*, 2008; Gin *et al.*, 2012), the glass dissolution rate in static conditions is divided into three successive regimes: the initial rate, a transition regime, and the residual rate regime (Fig. 21). The initial rate is the dissolution rate in very dilute conditions when no diffusion barrier slows down the kinetics. It is a property of the glass that strongly depends on its composition, on the temperature and on the pH of the solution (Frugier *et al.*, 2008). Secondary influencing parameters are the glass structure (Angeli *et al.*, 2018; Mascaraque *et al.*, 2017) and the chemistry of the solution such as its ionic strength (Icenhower and Dove, 2000) and the presence of complexing species (Tournié *et al.*, 2013). The transition regime corresponds to the progressive decrease of the dissolution rate by several orders of magnitude, which has two origins: the saturation of the solution with silica (affinity term Q/K_{eq} approaching 1) and the formation of an alteration layer or sub-layer with diffusion barrier properties (passivating layer). This alteration layer ends up in turn transforming into more stable products. At some time, an almost stationary regime establishes, when the diffusion rate of the reactive species through the passivating layer equals the rate of transformation of this layer into other, less passivating, products. This residual rate regime corresponds to the slow dissolution and transformation of the glass into a hydrated, porous silicate gel modified with other insoluble products (such as Zr and some amount of Al, La, Ca...). It can last a very long time, but it is also possible that at some moment, by exceeding some solubility product and/or induction time, a more insoluble and non-passivating Si-bearing product precipitates, which may take control of the kinetics and resume the dissolution of the glass by destroying the passivating layer (Fig. 21). This resumption regime has been observed in specific conditions of high pH and/or temperature, caused by the formation of zeolite phases (Fournier *et al.*, 2014).

The most extensive studies have been undertaken on the SON68 glass (inactive version of the R7T7 French nuclear glass). In a closed system composed of (initially) pure water at 50°C , the assessed residual rate of the SON68 glass is about $5.10^{-5} \text{ g m}^{-2} \text{d}^{-1}$, that is about 7 nm/year (Frugier *et al.*, 2008). This temperature of 50°C is considered representative of the actual temperature of the surface of the glass canisters over a very long time. The surface microstructure of a SON68 glass altered for 25 years in slowly flowing water equilibrated with granite, sand and (Ni,Cr) corrosion products, at 90°C and 100 bars, is depicted in Fig. 22 (Gin *et al.*, 2011). The alteration layer is composed of a hydrated glass, a porous gel and crystalline phyllosilicate phases in the outer part of the gel and on the surface. The dense layer that bears the passivating properties is located at the interface between the pristine glass and the hydrated glass, its diffusion coefficient is about $10^{-21} \text{ m}^2 \text{s}^{-1}$ characterizing a dense, solid phase.

Fig. 21 The three successive regimes of the dissolution rate in water of a nuclear borosilicate glass in static conditions: the initial rate, the transition regime, and the residual rate regime. The duration of these different regimes depends on both glass composition and alteration conditions. In specific conditions, a resumption regime can be observed for long times, due to silicate phases precipitation that may affect the passivating power of the alteration layer. Reproduced from Gin, S., Beaudoux, X., Angéli, F., Jégou, C., Godon, N., 2012. Effect of composition on the short-term and long-term dissolution rates of ten borosilicate glasses of increasing complexity from 3 to 30 oxides. *J. Non Cryst. Solids* 358, 2559–2570, p. 2665, with permission from Elsevier.

(a) NanoSIMS analysis of the interface between the pristine glass and the hydrated glass showing a 200 nm thick dense layer. The diffusion coefficient of boron through this layer is of the order $10^{-21} \text{ m}^2 \text{ s}^{-1}$ (b) TEM bright-field image of a FIB cross-section of the altered glass surface, showing the pristine glass and the alteration layer divided into a hydrated glass, a porous silicate gel and a top layer of phyllosilicates (phyllosilicates are also found in the porous gel). (c) TEM bright-field image of the phyllosilicates with an electron diffraction pattern of a crystallized grain. Reproduced from Gin, S., Guittouneau, C., Godon, N., *et al.*, 2011. Nuclear glass durability: New insight into alteration layer properties. *J. Phys. Chem. C* 115, 18696–18706. Authorized by The American Chemical Society.

Because of the nonlinear time and temperature dependency of the various reaction rates, and because of the coupling of these rates with transport processes through an evolving layer, there is no general theory to predict the kinetics of the dissolution, nor the nature, stability, and properties of the alteration layer. Predictions on the long-term can only be made based on geochemical models using parameters (equilibrium constants, kinetic parameters, diffusion coefficients) determined experimentally on a given glass-environmental system (Frugier *et al.*, 2008; Verney-Carron *et al.*, 2010). Archeological glasses or natural glasses altered for very long times in specific, stable conditions are used to validate the prediction capacities of these models (Verney-Carron *et al.*, 2008; Parruzot *et al.*, 2015).

Soc.* 95, 1297–1303 p. 5, with permission from John Wiley and Sons.

New mechanisms of glass dissolution and transformation at the interface between the pristine glass and the gel layer have been proposed, following dissolution mechanisms observed for silicate minerals (the coupled interface dissolution-precipitation model, CIDP) (Hellmann *et al.*, 2015). The development of analytical techniques with high spatial resolution, such as atomic probe tomography (APT) and advanced TEM techniques, as well as the use of isotopic tracers have allowed progress in the understanding of the chemical and microstructural changes of the alteration layer and of its diffusion properties (Gin *et al.*, 2017a). Particular attention has been drawn to the effect of environmental parameters such as the presence of iron corrosion products coming from the steel canister, or the composition of the groundwater (De Echave *et al.*, 2018). For instance, concerning the SON68 borosilicate glass, the presence of Fe²⁺ ions in the anoxic water (Michelin *et al.*, 2013), or the presence of Mg²⁺ ions (as in the groundwater of the Callovo-Oxfordian site envisaged for the disposal of the French nuclear glass) (Grambow, 2016) cause the precipitation of Fe-silicate or Mg-smectite phases (Thien *et al.*, 2012), which limit the dissolution rate drop by hindering the formation of a dense passivating layer.

In the scenario of the long-term evolution of the French disposal site established by ANDRA (Grambow, 2016), the nuclear glass will be first exposed to water in the vapor state, for a long period of time of several thousands of years, because of the hydrogen pressure produced by the anoxic corrosion of the steel canisters (Narayanasamy *et al.*, 2019). The alteration of the glass in a vapor state is specific and cannot be confused with the glass alteration in liquid water at high S/V. Water in vapor state or in the film adsorbed onto the glass surface has not the same dynamics and solvation properties as water in “bulk” liquid state. Moreover, the elements dissolved from the glass are not diluted in a liquid phase, so that the precipitation of secondary phases is rapid, modifying the glass surface chemistry (Majérus *et al.*, 2020). Further research is necessary to improve the understanding of the glass alteration in these specific conditions.

Glass-Ceramic Wasteforms

For a long time, the presence of crystals in nuclear glasses was regarded as undesirable because of the modification they may induce on the composition and durability against water of the surrounding glass and on the melting process, but now there is a general trend to accept partial crystallization for some waste if the containment of the final wasteform remains acceptable (Jantzen and Ojovan, 2019). Many studies have been performed to develop nuclear wasteforms consisting of a glassy phase and one or more crystalline phases able to incorporate non-separated HLW or separated long-life wastes in their structure (Donald, 2016; Caurant, 2017; McCloy and Goel, 2017). In the general case, such matrices made of crystals dispersed in a more or less abundant glassy phase are called glass composite materials (GCM) (Lee *et al.*, 2006). This is the case for instance of high waste loading wasteforms within which uncontrolled melt crystallization may occur during natural cooling of the melt (Figs. 4 and 23).

Glass-ceramics wasteforms correspond to a particular type of GCM containing small and numerous crystals homogeneously dispersed in a glassy phase that are obtained after controlled heat treatment of a glass containing the waste (nucleation + growth stages) (Fig. 24(a)) or controlled cooling of a melt, in order to produce a matrix with desired microstructure and crystalline phases in a durable residual glass. These crystalline phases are generally chosen according to their durability and their capacity to incorporate particular categories of elements present in the waste, such as long-lived radionuclides. Similar kind of matrices made of a durable glassy phase and homogeneously dispersed crystals of desired nature and size can also be obtained by sintering a

Fig. 24 Principle of the specific immobilization of long-life radionuclides in a glass-ceramic wasteform prepared by (a) crystallization (nucleation + growth) of a glass (referred to as parent glass) containing the radionuclides or (b) sintering a mixture of powders made of a glass frit and crystals in which are already incorporated the radionuclides.

mixture made of a glass powder and a crystalline phase already containing a particular category of elements present in HLW (encapsulation) (Fig. 24(b)).

The motivations for the studies on glass-ceramics for waste containment are varied:

- (1) Improvement of mechanical properties, thermal stability and chemical durability in comparison with glassy waste forms.
- (2) Research of more efficient and highly durable matrices than glasses to contain specifically separated long-life radionuclides in a highly durable crystalline phase (acting as first containment barrier) itself dispersed in a durable residual glass that can be considered as the second barrier against wasteform dissolution by water (Fig. 24(a)). In the case where the wastes to immobilize are not completely pure (for example actinide-rich waste with some fission products or other elements), the presence of the residual glass can be efficient to immobilize impurities.

Historically, in the 1970s, the first glass-ceramics which have been considered to contain nuclear wastes were prepared by heat treatment of glasses and the initial motivation was only to improve the mechanical and thermal properties of borosilicate glassy wasteforms (Donald *et al.*, 1997). The first complete work conducted on glass-ceramic matrices for containment of non-separated wastes was carried out in the 1980s on glass-ceramics containing CaTiSiO_5 (titanite) crystals dispersed within an aluminosilicate glassy matrix synthesized by nucleation and growth heat treatment of a glass containing TiO_2 (titanite is a mineral phase known for its capacity to incorporate actinides in its structure and to exhibit good chemical durability) (Hayward, 1988). More recently, several works have been performed on glass-ceramics containing zirconolite ($\text{CaZrTi}_2\text{O}_7$) crystals for the containment of separated MA that can be specifically isolated from HLW solutions by enhanced separation processes (Loiseau *et al.*, 2004; Caurant *et al.*, 2006). In this case, the aim was to obtain, after thermal treatment (nucleation + growth, Fig. 25) of a calcium aluminosilicate glass of suitable composition containing ZrO_2 , TiO_2 and MA surrogates (Ln), a wasteform acting as a double containment barrier for MA, with the objective of accommodating as much MA as possible in the zirconolite crystals (high partition coefficient) (Figs. 24(a) and 26). In the ideal case, the parent glass composition should be chosen such that the nucleation rate of the crystalline phase in the bulk is very high (to promote internal crystallization rather than crystallization from the surface) and that the partition coefficient of radionuclides between the crystalline phase and residual glass is high. In the case of the zirconolite-based glass-ceramics, the amount of crystalline phase and the partition coefficient of Ln between zirconolite crystals and the residual glass could be controlled by modification of the parent glass composition, for instance of the Al_2O_3 content (Fig. 26). Nevertheless, in spite of several composition changes performed for this system, a significant amount of Ln always remains in the residual glass and therefore does not benefit from a double containment barrier (Loiseau *et al.*, 2003; Caurant *et al.*, 2007a).

One alternative way to increase the partitioning ratio of the waste between the glass and the crystals is to prepare a wasteform not by crystallization of a glass already containing the waste as in glass-ceramics (Fig. 24(a)), but by encapsulating a highly durable crystalline phase containing the waste (prepared independently in a first stage) in a durable glass by sintering a mixture of two powders with adapted particle sizes (Fig. 24(b)). For instance, actinide wasteforms prepared by encapsulating highly durable pyrochlore ($\text{Gd}_2\text{Zr}_2\text{O}_7$, $\text{La}_2\text{Zr}_2\text{O}_7$) particles in a borosilicate or lead silicate glass have been proposed (Fig. 27) (Pace *et al.*, 2005; Boccacini *et al.*, 2007).

In all cases, the choice of the crystalline phase in which the radionuclides are expected to be incorporated is generally based on results from literature: knowledge of natural and highly durable crystalline phases (natural analogs) having incorporated natural

Fig. 25 Nucleation ($I = f(T)$) and crystal growth rate ($u = f(T)$) curves of zirconolite ($\text{CaZrTi}_2\text{O}_7$) crystals in the bulk of a calcium aluminosilicate glass containing ZrO_2 and TiO_2 and leading to zirconolite-based glass-ceramics (Fig. 24). I and u curves are well separated which limits crystallization during melt cooling and allows to control the preparation of glass-ceramics using a two-step thermal treatment (the picture given at the top of the figure shows the transformation of a Nd-doped glass into a glass-ceramic).

Fig. 26 Changes of the density of zirconolite crystals (Z) formed in the bulk of a glass-ceramic as a function of the variation of Al_2O_3 content (± 2.7 mol%) in a calcium aluminosilicate parent glass containing ZrO_2 and TiO_2 (T : titanite crystals (CaTiSiO_5) growing from glass surface). Glass-ceramics were prepared by a double heat treatment: nucleation at 810°C (2 h) and growth at 1050°C (2 h). Changes in the Al_2O_3 content in the parent glass strongly affect the zirconolite crystallization rate which can be explained by a competition between Al^{3+} , Ti^{4+} and Zr^{4+} for charge compensators in favor of Al^{3+} that destabilizes Ti^{4+} and Zr^{4+} and promotes zirconolite ($\text{CaZrTi}_2\text{O}_7$) crystallization. The zirconolite structure is shown at the top of the figure (MA^{3+} and Ln^{3+} can substitute for Ca^{2+} and Zr^{4+} with adapted compensation charge schemes). Modified from Caurant, D., Loiseau, P., Bardez, I., Gervais, C., 2007a. Effect of Al_2O_3 concentration on zirconolite ($\text{Ca}(\text{Zr,Hf})\text{Ti}_2\text{O}_7$) crystallization in $(\text{TiO}_2, \text{ZrO}_2, \text{HfO}_2)$ -rich SiO_2 - Al_2O_3 - CaO - Na_2O glasses. radionuclides (U, Th), studies on single-phase ceramics able to incorporate radionuclides and exhibiting very good long-term containment properties as demonstrated by leaching and irradiation tests.

In comparison with nuclear glasses, such GCM prepared either by the classical glass-ceramic technology (melting of a glass + crystallization thermal treatment) or by encapsulation (grinding + sintering) remain more complicated to synthesize than nuclear glasses, because of additional steps that can be difficult to achieve in a radioactive environment. Nevertheless, studies continue around the world on these types of matrices consisting of a highly durable crystalline phase able to incorporate actinide-rich waste dispersed in a glass (Liao *et al.*, 2017; Kong *et al.*, 2018). Moreover, the concept of double containment barrier in glass-ceramic wasteforms is also envisaged to increase the efficiency of the immobilization of non-radioactive hazardous wastes in comparison with homogeneous glassy wasteforms (Caurant *et al.*, 2017). This is the case for instance for chromium-rich industrial waste for which the possibility to prepare spinel-based glass-ceramics with a high partitioning ratio of chromium in the spinel ($\text{MgCr}_x\text{Al}_{2-x}\text{O}_4$) crystals has been demonstrated (Liao *et al.*, 2016).

Summary

About 70 years after the first studies on nuclear waste vitrification and more than 40 years after the start of industrial vitrification, oxide glasses – and mainly borosilicates – always remain the only host used to incorporate high level radioactive waste (HLW) from commercial and defense sources despite the many works that have been carried out on ceramic matrices. Their great structural flexibility, allowing them to accommodate almost all the elements present in the waste resulting from spent nuclear fuel reprocessing, their good self-irradiation resistance and chemical durability associated with their ease of fabrication by melting and casting explain the success of glassy wasteforms still today. Vitrification is now used in many countries around the world with constant improvements and the development of new types of melters.

Since the start of vitrification, a large number of works have been carried out to adapt glass formulation to the changes in waste composition, with an increasingly precise knowledge of the structure and properties of nuclear glasses, and in particular of the way the various elements present in the waste are incorporated into the glassy network and how this incorporation can be optimized by adapting the composition of the glass. Very extensive studies are still in progress in order to understand and to model the long-term behavior of nuclear glasses during their geological storage (alteration mechanisms in submerged aqueous medium or in the presence of water vapor, impact of internal irradiation on glass structure and properties). For a long time, the presence of crystals in nuclear glasses was regarded as undesirable because of the modification they may induce on their properties and on their impact on the melting process, but now there is a general trend to accept partial crystallization for some waste if the containment of the final wasteform remains acceptable, leading to glass composite materials (GCM). Belonging to this family of wasteforms, glass-ceramics that can be obtained by controlled crystallization of a glass bearing radionuclides can be envisaged for instance to immobilize actinide-rich waste.

The building of new nuclear power stations around the world with possible spent fuel reprocessing will lead in the future to an increasing need for waste vitrification. Moreover, the emergence of new radioactive wastes of various compositions coming for instance from the decommissioning and dismantling of old nuclear facilities and, in the more distant future, of new types of waste coming from new generations of nuclear power reactors requiring reprocessing of the spent fuel will still require many studies on new nuclear glass compositions for their immobilization.

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers may always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

CONTENT OF VOLUME 3

List of Contributors for Volume 3	ix
Content of All Volumes	xv

VOLUME 3

Overview: Electroceramics and Ceramics and Glasses in Energy Generation and Storage <i>Carmen Galassi</i>	1
Photovoltaics: Advanced Inorganic Materials <i>Abdelilah Slaoui and Reuben T Collins</i>	5
Ion Conducting Materials: Superionic Conductors and Solid-State Ionics <i>Junichi Kawamura</i>	17
Development, Structure, and Mechanical Properties of Sulfide Solid Electrolytes <i>Koji Ohara, Atsushi Sakuda, and Akitoshi Hayashi</i>	38
Solid Oxide Fuel Cells <i>Alessandra Sanson and Angela Gondolini</i>	49
Laser Processing of Energy Storage Materials <i>Heungsoo Kim and Alberto Piqué</i>	59
Aluminum, Gallium, and Indium Nitrides <i>Qilin Hua, Bei Ma, and Weiguo Hu</i>	74
Novel Nitride Phosphors <i>M Bettinelli</i>	84
Phosphors: VUV Excitation <i>Jean-Claude Krupa and AZMS Rahman</i>	89
Silicon Carbide Electronic Devices <i>PG Neudeck and GK Sujan</i>	93
Scintillator Crystals <i>D Klimm</i>	103
Ceramics for Laser Technologies <i>Jan Hostaša</i>	110
Ceramic Sensors for Industrial Applications <i>David Degler, Frank Allmendinger, and Nicolae Barsan</i>	125
Pyroelectric Crystals, Ceramics, and Thin Films for IR Sensors <i>Roger W Whatmore</i>	139
Superconducting Materials <i>Peter Majewski</i>	151
Superconductors: Borocarbides <i>Günter Fuchs, Karl-Hartmut Müller, and Vladimir N Narozhnyi</i>	162
The RABiTS Approach for Second Generation (2G) High Temperature Superconductors <i>Martin W Rupich</i>	174

Ferrite Ceramics at Microwave Frequencies: Applications and Characterization <i>Jean-Luc Mattei, Alexis Chevalier, and Vincent Laur</i>	183
Ferrite Magnets: Properties and Applications <i>Jean-Marie Le Breton</i>	206
Ferrites <i>PJ van der Zaag</i>	217
Multiferroic Composites <i>Xianfeng Liang, Huaihao Chen, Cheng Tu, Zhaoqiang Chu, Cunzheng Dong, Yifan He, Yuyi Wei, Yuan Gao, Hwaider Lin, and Nian X Sun</i>	225
Zinc-Oxide-Based Electronics and Photonics <i>David J Rogers, Ferechteh H Teherani, Eric V Sandana, and Philippe Bove</i>	241
Varistor Electrical Properties: Microstructural Effects <i>Zumret Topcagic and Thomas E Tsovilis</i>	254
Latest Trend of ZnO Multilayer Ceramic Varistors <i>Eiichi Koga, Yoshiko Higashi, and Michio Matsuoka</i>	272
Dielectric, Ferroelectric, Antiferroelectric, Relaxor, Piezoelectric Ceramics: Definitions and Main Applications <i>Floriana Craciun</i>	281
Electroceramics: Modeling of Sintering, Microstructure Evolution and Functional Properties <i>Constantin Hutanu, Vlad Alexandru Lukacs, and Liliana Mitoseriu</i>	295
BaTiO ₃ -Based Ceramics: Fundamentals, Properties and Applications <i>Vincenzo Buscaglia, Maria Teresa Buscaglia, and Giovanna Canu</i>	311
The PZT System <i>Florian Jean and Christian Courtois</i>	345
Lead-Free Piezoelectric Ceramics <i>Barbara Malič, Mojca Otoničar, Kristian Radan, and Jurij Koruza</i>	358
Electrostrictive Ceramics and Their Applications <i>Simone Santucci and Vincenzo Esposito</i>	369
Low-Loss Ceramics in Mobile Communications <i>K Wakino, H Tamura, and GK Sujan</i>	375
Small-Scale Energy Harvesting Devices for Smart Electronics <i>Sumanta Kumar Karan, Rammohan Sriramdas, Min-Gyu Kang, Yongke Yan, and Shashank Priya</i>	391
Multilayer Ceramic Actuators <i>K Uchino</i>	426
Multilayer Glass–Ceramic/Ceramic Composite Substrates <i>Jobin Varghese, Nina Joseph, and Heli Jantunen</i>	437
Functional Ceramics through Novel Chemical Approaches <i>K Kato, Y Torii, and G Majumdar</i>	452
Overview: Bioceramics and Bioreactive Glasses <i>Anne Leriche and Francis Cambier</i>	458
Bone as a Material: Lessons From Nature <i>Laura M O'Sullivan and Laoise M McNamara</i>	459
Overview of Substitutes for Bone Replacement: Natural and Synthetic Products <i>Nicolas Somers and Marie Lasgorceix</i>	473

New Trends in Ceramics for Orthopedics <i>Laurent Gremillard and Jérôme Chevalier</i>	493
New Trends in Ceramics for Dentistry <i>Paola Palmero</i>	501
Oxide Ceramics for Biomedical Applications <i>Corrado Piconi and Anna Tampieri</i>	511
Non-Oxide Ceramics as Biomaterials <i>Stuart Hampshire</i>	526
Carbon in Biomedical Engineering <i>Jill S Kawalec</i>	533
Yttria-Stabilized Zirconia as a Biomaterial: From Orthopedic Towards Dental Applications <i>Helen Reveron and Jérôme Chevalier</i>	540
ZTA Ceramics for Biomedical Applications <i>Frank Kern, Paola Palmero, and Wolfgang Burger</i>	553
Phosphates <i>David Grossin</i>	567
Apatitic and Tricalcic Calcium Phosphate-Based Bioceramics: Overview and Perspectives <i>Christophe Drouet and Christèle Combes</i>	575
Calcium Phosphates in Biomedical Engineering <i>Maria Canillas, Antonio H de Aza, and Miguel A Rodríguez</i>	595
Bioceramics in Regenerative Medicine <i>Simone Sprio, Anna Tampieri, Massimiliano Dapporto, Michele Iafisco, and Monica Montesi</i>	601
Bioactive Glasses and Glass-Ceramics <i>Francesco Baino</i>	614
Calcium Phosphate Cements <i>Aoife Culliton and Eamonn De Barra</i>	624
Bone Regeneration With Ceramics Scaffold <i>Vida Strasser and Maja Dutour Sikirić</i>	646
Advanced Processes for the Design of Customized Ceramic Medical Devices <i>Eric Champion and Patricia Pascaud-Mathieu</i>	662
Bioactive and Biodegradable Polymer-Based Composites <i>Lukas Gritsch and Aldo R Boccaccini</i>	674
Surface Treatment of Bioceramics <i>Nicolas Somers and Marie Lasgorceix</i>	701
Chemical Functionalization of Calcium Phosphate Bioceramic Surfaces <i>Chantal Damia, Amandine Magnaudeix, and Betty Laverdet</i>	716
Thermally Sprayed Materials for Biomedical Applications <i>Andreas Killinger and Rainer Gadow</i>	732
Design of Tissue Engineering Scaffold by Means of Mathematical Modeling <i>Stefan Scheiner</i>	750
Unconventional, Nature-Inspired Approaches to Develop Bioceramics for Regenerative Medicine <i>Anna Tampieri, Simone Sprio, Monica Sandri, Elisabetta Campodoni, Andrea Ruffini, Laura Mengozzi, and Silvia Panseri</i>	758
Assessment of Mechanical Properties of Bioceramics <i>Gilbert Fantozzi</i>	772

Mechanical Properties of Dental Ceramics <i>Fei Zhang and Jozef Vleugels</i>	784
Biological Assessment of Bioceramics: In Vitro and In Vivo Tests <i>Maria H Fernandes and Pedro de Sousa Gomes</i>	798
Zirconia Ceramics: Clinical and Biological Aspects in Dentistry <i>Andraž Kocjan, Tadej Mirt, Ralf-Joachim Kohal, Zhijian Shen, and Peter Jevnikar</i>	817
Subject Index	832

LIST OF CONTRIBUTORS FOR VOLUME 3

Frank Allmendinger
Furtwangen University, Tuttlingen, Germany

Francesco Baino
Politecnico di Torino, Turin, Italy

Nicolae Barsan
University of Tübingen, Tübingen, Germany

M Bettinelli
University of Verona, Verona, Italy

Aldo R. Boccaccini
University of Erlangen-Nuremberg, Erlangen, Germany

Philippe Bove
Nanovation, Chateaufort, France

Wolfgang Burger
Oximatec GmbH, Hochdorf, Germany

Maria Teresa Buscaglia
Institute of Condensed Matter Chemistry and Technologies for Energy, National Research Council, Genoa, Italy

Vincenzo Buscaglia
Institute of Condensed Matter Chemistry and Technologies for Energy, National Research Council, Genoa, Italy

Francis Cambier
Belgian Ceramic Research Centre, Mons, Belgium

Elisabetta Campodoni
Institute of Science and Technology for Ceramics–National Research Council, Faenza, Italy

Maria Canillas
Spanish National Research Council, Madrid, Spain

Giovanna Canu
Institute of Condensed Matter Chemistry and Technologies for Energy, National Research Council, Genoa, Italy

Eric Champion
University of Limoges, French National Centre for Scientific Research, Institute of Research for Ceramics, Limoges, France

Huaihao Chen
Northeastern University, Boston, MA, United States

Alexis Chevalier
University of Western Brittany, Brest, France

Jérôme Chevalier
National Institute of Applied Sciences of Lyon, Villeurbanne, France and University of Lyon, Villeurbanne Cedex, France

Zhaoqiang Chu
Northeastern University, Boston, MA, United States

Reuben T. Collins
Colorado School of Mines, Golden, CO, United States

Christèle Combes
CIRIMAT, Université de Toulouse, CNRS/INP/UPS, ENSIACET, Toulouse, France

Christian Courtois
Université Polytechnique Hauts-de-France, EA 2443 - Laboratoire des Matériaux Céramiques et Procédés Associés, Valenciennes, France

Floriana Craciun
Institute of Structure of Matter-CNR, Rome, Italy

Aoife Culliton
University of Limerick, Limerick, Ireland

Chantal Damia
French National Centre for Scientific Research, Institute of Research for Ceramics, University of Limoges, Limoges, France

Massimiliano Dapporto
National Research Council Institute of Science and Technology for Ceramics, Faenza, Italy

Antonio H. de Aza
Spanish National Research Council, Madrid, Spain

Eamonn De Barra
University of Limerick, Limerick, Ireland

David Degler
Furtwangen University, Tuttlingen, Germany

Pedro de Sousa Gomes
Faculty of Dental Medicine, BoneLab, U. Porto, Porto, Portugal and LAQV/REQUIMTE, U. Porto, Porto, Portugal

Cunzheng Dong
Northeastern University, Boston, MA, United States

Christophe Drouet
CIRIMAT, Université de Toulouse, CNRS/INP/UPS, ENSIACET, Toulouse, France

Maja Dutour Sikirić
Ruđer Bošković Institute, Zagreb, Croatia

Vincenzo Esposito
Technical University of Denmark, Kongens Lyngby, Denmark

Gilbert Fantozzi
University of Lyon, National Institute of Applied Sciences of Lyon, Materials: Engineering and Science (MATEIS), French National Centre for Scientific Research, Villeurbanne, France

Günter Fuchs
Leibniz Institute for Solid State and Materials Research, Dresden, Germany

Rainer Gadow
University of Stuttgart, Stuttgart, Germany

Carmen Galassi
National Research Council of Italy Institute of Science and Technology for Ceramics, Faenza, Italy

Yuan Gao
Winchester Technologies, LLC, Burlington, MA, United States

Angela Gondolini
National Research Council, Institute of Science and Technology for Ceramics, Faenza, Italy

Laurent Gremillard
National Institute of Applied Sciences of Lyon, Villeurbanne, France

Lukas Gritsch
University of Erlangen-Nuremberg, Erlangen, Germany and Clermont Auvergne University, Clermont Ferrand, France

David Grossin
Interuniversity Center of Materials Research and Engineering, University of Toulouse, French National Centre for Scientific Research, Toulouse, France

Maria H Fernandes
Faculty of Dental Medicine, BoneLab, U. Porto, Porto, Portugal and LAQV/REQUIMTE, U. Porto, Porto, Portugal

Stuart Hampshire
Bernal Institute, University of Limerick, Limerick, Ireland

Akitoshi Hayashi
Osaka Prefecture University, Osaka, Japan

Yifan He
Northeastern University, Boston, MA, United States

Yoshiko Higashi
Panasonic Co. Ltd., Osaka, Japan

Jan Hostaša
National Research Council of Italy, Institute of Science and Technology for Ceramics, Faenza, Italy

Weiguo Hu
Beijing Institute of Nanoenergy and Nanosystems, Chinese Academy of Sciences, Beijing, China and University of Chinese Academy of Sciences, Beijing, China

Qilin Hua
Beijing Institute of Nanoenergy and Nanosystems, Chinese Academy of Sciences, Beijing, China and University of Chinese Academy of Sciences, Beijing, China

Constantin Hutanu
1 Decembrie 1918 University, Alba Iulia, Romania

Michele Iafisco
National Research Council Institute of Science and Technology for Ceramics, Faenza, Italy

Heli Jantunen
University of Oulu, Oulu, Finland

Florian Jean
Université Polytechnique Hauts-de-France, EA 2443 - Laboratoire des Matériaux Céramiques et Procédés Associés, Valenciennes, France

Peter Jevnikar
University of Ljubljana, Faculty of Medicine, Ljubljana, Slovenia

Nina Joseph
University of Oulu, Oulu, Finland

Min-Gyu Kang
Pennsylvania State University, University Park, PA, United States

Sumanta Kumar Karan
Pennsylvania State University, University Park, PA, United States

K. Kato
National Institute of Advanced Industrial Science and Technology, Nagoya, Japan

Jill S. Kawalec
College of Podiatric Medicine, Kent State University, Independence, OH, United States

Junichi Kawamura
IMRAM, Tohoku University Katahira, Sendai, Japan

Frank Kern
University of Stuttgart, Stuttgart, Germany

Andreas Killinger
University of Stuttgart, Stuttgart, Germany

Heungsoo Kim
Materials Science & Technology Division, United States
and Naval Research Laboratory, Washington, D.C.,
United States

D. Klimm
Leibniz Institute for Crystal Growth, Berlin, Germany

Andraž Kocjan
Department for Nanostructured Materials, Jožef Stefan
Institute, Ljubljana, Slovenia

Eiichi Koga
Panasonic Co. Ltd., Osaka, Japan

Ralf-Joachim Kohal
Medical Center - University of Freiburg, Center for
Dental Medicine, Department of Prosthetic Dentistry,
Faculty of Medicine, University of Freiburg, Freiburg,
Germany

Jurij Koruza
Technical University of Darmstadt, Darmstadt, Germany

Jean-Claude Krupa
Institute of Nuclear Physics, Orsay, France

Marie Lasgorceix
Polytechnic University of Hauts-de-France, Valenciennes,
France

Vincent Laur
University of Western Brittany, Brest, France

Betty Laverdet
French National Centre for Scientific Research, Institute
of Research for Ceramics, University of Limoges,
Limoges, France

Jean-Marie Le Breton
Normandie University, UNIROUEN, INSA Rouen,
CNRS, GPM, Rouen, France

Anne Leriche
Polytechnic University Hauts-de-France, Valenciennes,
France

Xianfeng Liang
Northeastern University, Boston, MA, United States

Hwaider Lin
Winchester Technologies, LLC, Burlington, MA, United
States

Vlad Alexandru Lukacs
Alexandru Ioan Cuza University of Iasi, Iasi, Romania

Bei Ma
Chiba University, Chiba, Japan

Amandine Magnaudeix
French National Centre for Scientific Research, Institute
of Research for Ceramics, University of Limoges,
Limoges, France

Peter Majewski
University of South Australia, Adelaide, Australia

G. Majumdar
Jadavpur University, Kolkata, India

Barbara Malič
Jožef Stefan Institute, Ljubljana, Slovenia

Michio Matsuoka
Panasonic Co. Ltd., Osaka, Japan

Jean-Luc Mattei
University of Western Brittany, Brest, France

Laoise. M. McNamara
National University of Ireland Galway, Galway, Ireland

Laura Mengozzi
Institute of Science and Technology for Ceramics–
National Research Council, Faenza, Italy

Tadej Mirt
University of Ljubljana, Faculty of Medicine, Ljubljana,
Slovenia

Liliana Mitoseriu
Alexandru Ioan Cuza University of Iasi, Iasi, Romania

Monica Montesi
National Research Council Institute of Science and
Technology for Ceramics, Faenza, Italy

Karl-Hartmut Müller
Leibniz Institute for Solid State and Materials Research,
Dresden, Germany

Vladimir N. Narozhnyi
Russian Academy of Sciences, Moscow, Russia

P.G. Neudeck
NASA Glenn Research Center at Lewis Field, Cleveland,
OH, USA

Koji Ohara
Japan Synchrotron Radiation Research Institute, Hyogo,
Japan

Mojca Otoničar
Jožef Stefan Institute, Ljubljana, Slovenia

Laura. M. O'Sullivan
National University of Ireland Galway, Galway, Ireland

Paola Palmero
Department of Applied Science and Technology,
Politecnico di Torino, Italy and The Polytechnic
University of Turin, Torino, Italy

Silvia Panseri
*Institute of Science and Technology for Ceramics–
National Research Council, Faenza, Italy*

Patricia Pascaud-Mathieu
*University of Limoges, French National Centre for
Scientific Research, Institute of Research for Ceramics,
Limoges, France*

Corrado Piconi
*Institute for the Science and Technology of Ceramics,
National Research Council, Faenza, Italy*

Alberto Piqué
*Materials Science & Technology Division, United States
and Naval Research Laboratory, Washington, D.C.,
United States*

Shashank Priya
*Pennsylvania State University, University Park, PA,
United States*

Kristian Radan
Jožef Stefan Institute, Ljubljana, Slovenia

A.Z.M.S. Rahman
*The Ohio State University, Columbus, OH, United
States*

Helen Reveron
University of Lyon, Villeurbanne Cedex, France

Miguel A. Rodríguez
Spanish National Research Council, Madrid, Spain

David J. Rogers
Nanovation, Chateaufort, France

Andrea Ruffini
*Institute of Science and Technology for Ceramics–
National Research Council, Faenza, Italy*

Martin W. Rupich
*American Superconductor Corporation, Ayer, MA,
United States*

Atsushi Sakuda
Osaka Prefecture University, Osaka, Japan

Eric V. Sandana
Nanovation, Chateaufort, France

Monica Sandri
*Institute of Science and Technology for Ceramics–
National Research Council, Faenza, Italy*

Alessandra Sanson
*National Research Council, Institute of Science and
Technology for Ceramics, Faenza, Italy*

Simone Santucci
*Technical University of Denmark, Kongens Lyngby,
Denmark*

Stefan Scheiner
*TU Wien (Vienna University of Technology), Vienna,
Austria*

Zhijian Shen
*Department of Materials and Environmental Chemistry,
Arrhenius Laboratory, Stockholm University, Stockholm,
Sweden*

Abdelilah Slaoui
CNRS-University of Strasbourg, Strasbourg, France

Nicolas Somers
*Polytechnic University of Hauts-de-France, Valenciennes,
France and University Polytechnic Hauts-de-France,
Valenciennes, France*

Simone Sprio
*Institute of Science and Technology for Ceramics–
National Research Council, Faenza, Italy and National
Research Council Institute of Science and Technology for
Ceramics, Faenza, Italy*

Rammohan Sriramdas
*Pennsylvania State University, University Park, PA,
United States*

Vida Strasser
Ruđer Bošković Institute, Zagreb, Croatia

G.K. Sujan
University of Malaya, Kuala Lumpur, Malaysia

Nian X. Sun
*Northeastern University, Boston, MA, United States and
Winchester Technologies, LLC, Burlington, MA, United
States*

Anna Tampieri
*Institute for the Science and Technology of Ceramics,
National Research Council, Faenza, Italy*

H. Tamura
Murata Manufacturing Co., Ltd., Kyoto, Japan

Ferechteh H. Teherani
Nanovation, Chateaufort, France

Zumret Topcagic
Raycap Group, Komenda, Slovenia

Y. Torii
*National Institute of Advanced Industrial Science and
Technology, Nagoya, Japan*

Thomas E. Tsovilis
Aristotle University of Thessaloniki, Thessaloniki, Greece

Cheng Tu
Northeastern University, Boston, MA, United States

K. Uchino
The Penn State University, University Park, PA, USA

P.J. van der Zaag
Philips Research Laboratories, Eindhoven, The Netherlands

Jobin Varghese
University of Oulu, Oulu, Finland and Fraunhofer Institute for Ceramic Technologies and Systems IKTS, Dresden, Germany

Jozef Vleugels
Department of Materials Engineering, KU Leuven, Heverlee, Belgium

K. Wakino
Murata Manufacturing Co., Ltd., Kyoto, Japan

Yuyi Wei
Northeastern University, Boston, MA, United States

Roger W. Whatmore
Imperial College London, London, United Kingdom

Yongke Yan
Pennsylvania State University, University Park, PA, United States

Fei Zhang
Department of Oral Health Sciences, BIOMAT & University Hospitals Leuven, KU Leuven, Leuven, Belgium and Department of Materials Engineering, KU Leuven, Heverlee, Belgium

CONTENT OF ALL VOLUMES

List of Contributors for Volume	ix
Editor Biographies	xxiii
Preface	xxv

VOLUME 1

Overview: Manufacture of Ceramics and Microstructural Developments in Ceramics <i>Francis Cambier and Anne Leriche</i>	1
Synthesis of Oxide and Non-Oxide Advanced Ceramics <i>Prashant N Kumta</i>	2
Synthesis of Ceramic Powders by Wet Chemical Routes <i>Paola Palmero</i>	27
Self-Propagating High-Temperature Synthesis <i>Jerzy Lis</i>	40
Hydrothermal Synthesis <i>Ender Suvaci and Emel Özel</i>	59
Ultrasonic Sprayed Aerosol for Ultrafine Ceramic Powder Synthesis <i>Sylvie Foucaud and Yann Leconte</i>	69
Calcination and Phase Transformations <i>Gary L Messing</i>	83
Preceramic Polymers as Precursors of Advanced Ceramics: The Polymer-Derived Ceramics (PDCs) Route <i>Yuji Iwamoto, Günter Motz, Emanuel Ionescu, and Samuel Bernard</i>	93
Organic Additives in Ceramic Processing <i>Anne Aimable and Thierry Chartier</i>	103
Powder Mixing and Grinding Processes for Ceramics <i>David Houivet and Jérôme Bernard</i>	112
Powder Granulation and Compaction <i>Michele Dondi</i>	136
Colloid Casting Processes: Slip Casting, Centrifugal Casting, and Gel Casting <i>Nur S Yüzbaşı and Thomas Graule</i>	146
Processing of Ceramics by Direct Coagulation Casting <i>Margarida Almeida and Joaquim M Vieira</i>	154
Extrusion <i>Stuart Blackburn and Marcin Szymiczek</i>	162
Ceramic Injection Molding <i>Moritz v Witzleben and Tassilo Moritz</i>	179

Tape Casting and Lamination <i>Eric R Twiname</i>	189
Freeze Casting <i>Dominique Hautcoeur</i>	195
Additive Manufacturing <i>Andrea Zocca, Giorgia Franchin, Paolo Colombo, and Jens Günster</i>	203
Green Machining of Ceramics <i>Fabrice Petit</i>	222
Screen Printing <i>Danjela Kuscser</i>	227
Sintering of Ceramics: An Overview <i>Anne Leriche, Francis Cambier, and Stuart Hampshire</i>	233
Solid-State Sintering <i>John E Blendell and Wolfgang Rheinheimer</i>	249
Liquid Phase Sintering: Fundamentals <i>Suk-Joong L Kang</i>	258
Viscous Sintering <i>George W Scherer</i>	265
Hot Pressing and Hot Isostatic Pressing <i>Mathias Herrmann and Jan Räthel</i>	270
Reaction Sintering <i>Carmen Baudín</i>	278
Flash Sintering and Other Rapid Sintering Techniques <i>David Salamon</i>	286
Spark Plasma Sintering <i>Umberto Anselmi-Tamburini</i>	294
Cold Sintering and Hydrothermal Sintering <i>Graziella Goglio, Arnaud Ndayishimiye, Catherine Elissalde, and Clive A Randall</i>	311
Microwave Sintering of Ceramics <i>Jean-Marc Chaix</i>	327
Porous Ceramics Processing <i>Manabu Fukushima, Akihiro Shimamura, Paolo Colombo, Hideki Hyuga, Tatsuki Ohji, and Yu-ichi Yoshizawa</i>	342
Porous Ceramics Including Fibrous Insulation, Structure and Properties of <i>M Fukushima, T Ohji, P Colombo, and Y-I Yoshizawa</i>	346
Control of the Microstructure in Ceramics <i>Anne Leriche, Stuart Hampshire, and Francis Cambier</i>	349
Templated Grain Growth of Textured Ceramics <i>Gary L Messing</i>	367
Functionally Graded Ceramics <i>Omer Van der Biest and Achim Neubrand</i>	374
Transparent Ceramics: Materials, Processing, Properties and Applications <i>Marc Rubat du Merac</i>	399
Geopolymers and Geopolymer-Derived Composites <i>Waltraud M Kriven</i>	424

Overview: Characterization and Modelling of Ceramics and Glasses <i>Michael Pomeroy and Stuart Hampshire</i>	439
Ceramic Genomics: Total Bond Order Density <i>Wai-Yim Ching</i>	441
Predictive Modeling of Ceramic Materials <i>Sarah Guerin, Syed AM Tofail, and Damien Thompson</i>	475
Molecular Dynamics Simulations of Glass Structure <i>Mattias Edén</i>	481
Computation of Phase Diagrams for Ceramics <i>Sara Serena, Angel Caballero, Antonio H de Aza, and Maria A Sainz</i>	498
Characterization of Ceramic Powders <i>Martin J Murtagh and Navin Venugopal</i>	517
Amorphous Materials: Vibrational Spectroscopy <i>PF McMillan</i>	530
MAS NMR Analysis of Ceramics and Glasses <i>Yajie Gao</i>	536
X-Ray Powder Diffraction <i>Scott T Mixture</i>	549
Case Studies in the X-ray Diffraction of Ceramics <i>Maurice Gonon</i>	560
Introduction to Transmission Electron Microscopy; The Basics <i>Ann-Katrin Fetzner, Maximilian Trapp, Stefan Lauterbach, and Hans-Joachim Kleebe</i>	578
High Resolution Analytical Electron Microscopy of Ceramics and Glasses <i>Jennifer Cookman, Michele Conroy, and Ursel Bangert</i>	600
Introduction to Three Dimensional Electron Crystallography <i>Andrew Stewart and Ute Kolb</i>	618
Preparation of Ceramic, Glass-Ceramic and Glasses for Microstructural Examination <i>Michael J Pomeroy</i>	634
Scanning Electron Microscopy for Ceramics and Glasses <i>Michael J Pomeroy</i>	651
Fractography: Brittle Materials <i>John J Mecholsky, Jr.</i>	662
Thermal Analysis Techniques for Technical Ceramics and Glasses <i>Michael J Pomeroy</i>	676
High-Temperature Characterization of Glasses and Melts <i>Sohei Sukenaga and Hiroyuki Shibata</i>	689
Overview: Mechanical and Physical Properties and Property Testing of Ceramics and Glasses <i>Anne Leriche and Francis Cambier</i>	704
Elastic and Inelastic Behavior of Ceramics <i>Daniele Mari and Robert Schaller</i>	705
Indentation of Ceramics <i>Emilio Jiménez-Piqué</i>	718
Contact Damage Resistance and Tribological Behavior of Ceramic/Carbon Nanostructure Composites <i>Manuel Belmonte</i>	733

Methods of Determination of Young's Modulus and Tensile, Flexural and Compressive Strength <i>Sylvain Meille</i>	745
Fracture Toughness Measurement <i>Tanja Lube</i>	762
R-Curve Behavior of Ceramics <i>Marc J Anglada</i>	775
Subcritical Crack Growth: Basic Relations and Experimental Evaluation <i>Malika Saâdaoui</i>	797
Subcritical Crack Growth: Modeling of the v-K Curve in Different Environments <i>Raul Bermejo</i>	811
Ceramics: Transformation Toughening <i>DB Marshall and RHJ Hannink</i>	818
Mixed-Mode Fracture and Microstructural Aspects of Crack Propagation <i>Delia Gutiérrez-Campos and Yuk Ming X Hung-Hung</i>	823
R-Ratio and Microstructure Effects <i>Delia Gutiérrez-Campos, Eliana Pinto-González, and Elvira Saab-Llatas</i>	841
Thermal Properties of Ceramic Materials <i>David S Smith and Benoît Naït-Ali</i>	855
Thermal Shock Behavior of Ceramics: Fundamentals and Thermal Shock Resistance Parameters <i>Carmen Baudín</i>	867
Thermal Shock and Thermal Fatigue Behavior of Ceramics: Microstructural Effects <i>Gilbert Fantozzi and Malika Saâdaoui</i>	879
Creep Behavior of Ceramics <i>Gilbert Fantozzi and Arturo Dominguez-Rodriguez</i>	891
Nonoxide Ceramics, Creep and Creep Rupture of: Silicon Nitrides and Silicon Carbides <i>SM Wiederhorn</i>	908
Dislocations in Ceramic Materials <i>Jacques Rabier</i>	911
Corrosion of Ceramics in Aqueous Environments <i>Mathias Herrmann</i>	921
Corrosion and Degradation of Glass <i>Dagmar Galusková and Dušan Galusek</i>	932

VOLUME 2

Overview: Oxide Ceramics and Non-oxide Ceramics <i>Stuart Hampshire and Michael Pomeroy</i>	1
Structural and Thermostructural Ceramics <i>Jon Binner and Tammana SRC Murthy</i>	3
Alumina, Structure and Properties <i>Carmen Baudín</i>	25
Low Thermal Expansion Ceramic and Glass-Ceramic Materials <i>Pascal Pilate and Florimond Delobel</i>	47

Mullite: Structure and Properties <i>Gi��le L Lecomte-Nana and Aghiles Hammas</i>	59
Aluminum Titanate, Structure and Properties <i>Salvador Bueno and Carmen Baud��n</i>	76
Zirconia Ceramics, Structure and Properties <i>Anne Leriche, Francis Cambier, and Helen Reveron</i>	93
Si ₃ N ₄ -Ceramics: An Introduction <i>MJ Hoffmann</i>	105
Si ₃ N ₄ Ceramics, Structure and Properties <i>Monika Tatarkov��, Peter Tatarko, and Pavol ��ajgal��k</i>	109
SiALONs and the Representation of Phase Relationships <i>Stuart Hampshire</i>	119
Si-Al-O-N Ceramics, Structure and Properties <i>Ali ��elik and Servet Turan</i>	128
Aluminum Nitride and ALON Ceramics, Structure and Properties of <i>JW McCauley</i>	144
SiC Ceramics, Structure, Processing and Properties <i>Young-Wook Kim and Rohit Malik</i>	150
High Thermal Conductivity Ceramics <i>Mikito Kitayama</i>	165
MAX Phases, Structure, Processing, and Properties <i>Nick Goossens, Bensu Tunca, Thomas Lapauw, Konstantina Lambrinou, and Jozef Vleugels</i>	182
ZrB ₂ , HfB ₂ , OsB ₂ and IrB ₂ Boride Ceramics: Processing, Structure, and Properties <i>Nina Orlovskaya, Holden Hyer, Yongho Sohn, Mykola Lugovy, Gurdial Blugan, Thomas Graule, Jakob Kuebler, Sergey Yarmolenko, Jagannathan Sankar, and Michael J Reece</i>	200
Directionally-Solidified Eutectic Oxide Ceramics <i>VM Orera^{��} and J Llorca</i>	216
Overview: High-Performance Ceramics and Ceramic Composites <i>Michael Pomeroy</i>	225
Ceramic Matrix Composites With Roughly Equiaxed Reinforcements: Microstructure and Mechanical Behavior <i>Gilbert Fantozzi and J��r��me Chevalier</i>	227
Nanoscale Ceramic Composites <i>GS Thompson and MP Harmer</i>	240
Ceramic Matrix Graphene and Carbon Nanotube Composites <i>Katalin Bal��zsi, M��nika Furk��, and Csaba Bal��zsi</i>	243
Short Fiber Ceramic Matrix Composites (SF-CMCs) <i>Walter Krenkel, Stefan Flauder, and Georg Puchas</i>	260
Glass and Glass-Ceramic Matrix Composites for Advanced Applications: Part I: Properties and Manufacturing Technologies <i>Dino Boccaccini, Maria Cannio, Enrico Bernardo, and Aldo R Boccaccini</i>	277
Glass and Glass-Ceramic Matrix Composites for Advanced Applications: Part II: Applications <i>Dino Boccaccini, Maria Cannio, Enrico Bernardo, and Aldo R Boccaccini</i>	288

^{  }Deceased.

High Performance Fibers <i>AR Bunsell</i>	304

Overview: Electroceramics and Ceramics and Glasses in Energy Generation and Storage

Carmen Galassi[☆], National Research Council of Italy Institute of Science and Technology for Ceramics, Faenza, Italy

© 2021 Elsevier Inc. All rights reserved.

Over the last two decades Electroceramics and Ceramics and Glasses in Energy Generation and Storage, perhaps the most economically important member of engineered ceramics, have become one of the most important research areas in materials science both through improvements in basic knowledge and their significant growing technological impact.

Electroceramics include advanced ceramic materials that are used in a wide variety of electrical, optical and magnetic applications.

Technology and device applications drive research in this growing field that includes ionically conducting, semiconducting, superconducting, magnetic and dielectric ceramics, used in domains as diverse as energy conversion and storage, consumer electronics and communication, medicine and health care, transportation, industrial production, power engineering.

The Section “Electroceramics and Ceramics and Glasses in Energy Generation and Storage” covers all the main topics related, from basics of the material science to the processing technologies and several applications. The chapters are grouped following the main focus, and the reader will be helped by the keywords as many of them cover different aspects like material properties, characterizations and applications.

The First Five Chapters are Related to Energy Conversion and Storage

Photovoltaics

Advanced Inorganic Materials: the commercial first PV modules are based on single-crystal and multicrystalline silicon wafers, the second generation is based on inorganic semiconductor thin films; the next generation is driven by concepts aimed at ultra-high efficiency and/or ultra-low cost regimes and involving nanotechnologies, multiple junctions, and bandgap engineering.

Ion Conducting Materials

Superionic Conductors and Solid-State Ionics: review of solid electrolytes which show purely ionic conduction and mixed conductors which show both ionic and electronic conduction and their applications in sensors, high power batteries, electrolysis of gaseous molecules and gas separation.

Development, Structure, and Mechanical Properties of Sulfide Solid Electrolytes: the sulfide solid electrolytes with a high lithium ion conductivity and their mechanical properties are addressed.

Solid Oxide Fuel Cells

The chapter describes the types of SOFCs, technological trends in the recent years and the progress in material's development and processing (electrolytes, anode substrates and anodes, cathode, interconnect, protective and contact coatings, sealings).

Laser Processing of Energy Storage Materials

The laser-based processing techniques for the fabrication of energy storage devices including three laser-based processing techniques (LIFT, PLD and LSM) for the fabrication of energy storage devices are reviewed.

Six Chapters Survey Materials for Electronics and Optoelectronics

Aluminum, Gallium, and Indium Nitrides

Outlook of fundamental properties of Aluminum, Gallium, and Indium Nitrides and insight into the potential applications of GaN-based electronic/optoelectronic.

[☆]Now research fellow at Politecnico di Milano, Department of Mechanical Engineering.

Novel Nitride Phosphors

Nitride and oxynitride families have proved to be excellent hosts for the development of efficient phosphors for white pcLEDs, emitting all over the visible range; development of the perfect phosphors for LEDs, and nitride and oxynitride materials will play an important role for future applications.

Phosphors

VUV Excitation: as far as vacuum ultraviolet (VUV) optical excitations are concerned, the most suitable materials are the large band gap inorganic lattices activated by rare earth ions. These phosphors are mainly sintered oxo (phosphates, borates, aluminates, etc.), oxofluoride or fluoride compounds.

Silicon Carbide Electronic Devices

Silicon Carbide is useful for realizing short-wavelength blue and UV optoelectronics; SiC RF devices are applied in high-frequency solid-state high-power amplification; silicon-on-insulator circuits can perform complex digital and analog signal-level functions up to 300°C.

Scintillator Crystals

NaI and other low melting point halide crystals are often used as scintillator crystals. They are suitable for easy working conditions (T, p, energy of radiation). Issues to maintain high optical quality are discussed.

Ceramics for Laser Technologies

The ceramics for laser technologies are single-phase polycrystalline materials, doped with transition metals or lanthanides. They are transparent in the wavelength range of the absorption and emission range and they must have the thermal and mechanical properties to withstand the laser operation.

Two Chapters are Specifically Dedicated to Ceramics for Sensors

Ceramic Sensors for Industrial Applications

Different gas sensors types (pellistor-type gas sensors, gas sensors based on solid ionic conductors and chemoresistive gas sensors based on semiconducting metal oxides) based on ceramic materials and their working principles are presented.

Pyroelectric Crystals, Ceramics, and Thin Films for IR Sensors

IR Sensors for detection of radiation in the infrared radiation (IR) bands of 3–5 mm and especially 8–14 mm are introduced. Pyroelectric detectors have found a huge range of applications in products ranging from fire alarms to intruder detectors, in instrumentation such as gas analysis, and in thermal imaging.

Three Chapters Deal With Superconducting Materials

Superconducting Materials

Survey of the different types of superconducting materials, including an introduction to superconductivity and its important fundamental parameters. The review also introduces the major superconducting materials which currently represent the basis for superconducting devices and which may be important candidates for future application. Fundamental materials aspects of these materials and how they affect their superconducting properties are presented as well.

Superconductors

Borocarbides: rare-earth nickel borocarbides are magnetic superconductors showing both, coexistence and competition of superconductivity and magnetic order. The interplay between superconductivity and magnetism is discussed for $\text{HoNi}_2\text{B}_2\text{C}$.

The RABiTS Approach for Second Generation (2G) High Temperature Superconductors: overview of the Rolling Assisted Bi-axially Textured Substrate (RABiTS™) process for fabricating long length high temperature superconducting (HTS) wire based on the $(\text{RE})\text{Ba}_2\text{Cu}_3\text{O}_{7-x}$ materials ((RE)BCO) where RE is a rare earth. The RABiTS process is one of three template technologies developed for the roll-to-roll manufacturing of long length.

Four Chapters Introduce the Ceramic Magnetic Materials

Ferrite Ceramics at Microwave Frequencies: Applications and Characterization

Ferrite ceramics with their magnetic properties and low loss are applied as passive microwave components operating over a wide range of frequencies. The basics and main properties are surveyed with specific reference to the application at Microwave Frequencies.

Ferrite Magnets

Properties and Applications: permanent magnets materials are magnetic materials that can keep their magnetization once they are submitted to a magnetic field. They are denoted as hard magnetic materials and their magnetization remains stable at the temperature of use.

Ferrites: soft ferrites with cubic, spinel lattice structure have found widespread use in electronic applications as inductor or transformer cores; their applications and new developments in thin films.

Multiferroic Composites: these extremely interesting materials with coupled ferromagnetic and ferroelectric orders with huge potential for technological applications. Their multifunctional properties of multiferroic composites facilitate the development of novel electronic devices for various sensing, transduction, and antenna applications. Their characterization, modeling and applications (sensor, inductor, filters, antennas), are surveyed.

Three Chapters are Focused on Zinc Oxide

Zinc-Oxide-Based Electronics and Photonics

Overview of the existing and emerging ZnO electronics/photonics applications (Varistors, Optical Filtering, Transparent Conductors, solar cell technologies, Transparent/Flexible Electronics, Light Emitters, Sensors).

Varistor Electrical Properties: Microstructural effects

Even though ZnO varistors have been extensively investigated the last four decades, the research on this topic is still noticeably dynamic and active. This work correlates some aspects of the varistor technology and their microstructural effects on the macroscopic electrical properties. Emphasis is given to academic and industrial research results.

Latest Trend of ZnO Multilayer Ceramic Varistors

Multilayer ceramic varistors (MLCVs) are usually employed as protection devices from overvoltages; new varistor material composition is introduced but also MLCVS with a discharge cavity between internal electrodes.

Nine Chapters are Focused on Dielectric/Ferroelectric/Piezoelectric/Electrostrictive Ceramic Materials

Dielectric, Ferroelectric, Antiferroelectric, Relaxor, Piezoelectric Ceramics

Definitions and Main Applications: the properties of dielectric crystalline media for different structures are defined and the main types of dielectric ceramics interesting for applications are presented. In the second section, basic concepts related to dielectrics, piezoelectric, ferroelectric, antiferroelectric, and relaxor ceramics are introduced.

Electroceramics

Modeling of Sintering, Microstructure Evolution and Functional Properties: a few examples of theoretical and modeling approaches regarding the description of ferroelectric polycrystalline ceramics, in particular ferroelectrics, are presented: models for describing the sintering process and microstructure evolution, including the description of the role of defects, interfaces, grain boundaries and size effects on the electrical properties.

BaTiO₃-Based Ceramics

Fundamentals, Properties and Applications: survey of 70 years of continuous investigation BaTiO₃, the first ferroelectric and piezoelectric ceramic developed for commercial applications. It is still widely used, especially as a high permittivity dielectric in multilayer ceramic capacitors (MLCCs) and as a semiconducting material in thermistors with positive temperature coefficient of

resistivity (PTCR). Barium titanate still attracts great attention as a model ferroelectric system and key component of materials for applications in capacitors, lead-free piezoelectric devices, ceramics and composites for energy storage.

The PZT System

lead zirconate titanate (PZT) constitute the best family of piezoelectric and ferroelectric materials suitable for integration into devices such as piezoelectric actuators, sensors and transducers. Crystal structure, synthesis route, piezoelectric properties and their modification by acceptor or donor doping or valence compensation and correlations between microstructure and performance relations are addressed.

Lead-Free Piezoelectric Ceramics: three main groups of lead-free perovskite piezoelectrics, KNN-, NBT-, and BT-based, their structure, phase relations, properties, synthesis and processing are focussed, linked to applications. Environmental and health concerns are discussed.

Electrostrictive Ceramics and Their Applications: in-depth analysis of the physics of electrostriction, types of electrostrictive materials, comparison with piezoelectrics and applications Survey of the behind the properties and applications (mainly micro-electromechanical systems).

Low-Loss Ceramics in Mobile Communications: the importance of low-loss ceramics in high-frequency applications is growing with their use for mobile communications, intelligent transportation systems (ITSs), wireless local area networks (LANs), bluetooth systems, etc. Their application in dielectric resonators, multilayer substrates, multichip modules (MCMs), and dielectric antennas and ceramic capacitors is surveyed.

Small-scale Energy Harvesting Devices for Smart Electronics: energy harvesting from ambient mechanical vibrations and stray magnetic fields is described with emphasis on fundamentals governing the material selection and implementation. Small-scale energy harvesting devices are explored with relevance towards wireless sensors and biomedical applications.

Multilayer Ceramic Actuators

Development history on the improvement of reliability and durability in multilayer actuators, and various applications, with a particular emphasis on recent three researchers: Pb-free piezoelectric materials, base metal (Cu) internal electrode, and diesel injection valve application.

Two Chapters are Focused on Technologies That are Relevant for Several Materials and Applications

Multilayer Glass–Ceramic/Ceramic Composite Substrates: Review of the processing of multilayer glass–ceramic/composite substrates prepared by HTCC, LTCC, ULTCC. Survey of UHTCs and cold sintering/room temperature fabrication/upside-down composite fabrication and of the production of substrates and packages by combining functional layers and passive electronic components in one multilayer co-sinterable module.

Functional Ceramics Through Novel Chemical Approaches

Chemical modification and processing of different thin films are presented. KTN thin films prepared by the chemical solution deposition method and UV-processing used for the patterning of the films are focused. The epitaxy and optical transmittance of KTN films from the EGME-modified precursor combined with UV treatment is discussed.

Photovoltaics: Advanced Inorganic Materials

Photovoltaic Market

By 2050 world energy consumption is predicted to grow from the present 13–30 TW yr. To meet this huge demand, the global energy sector will be facing two main pressing issues, declining fossil reserves and climate change due to man-made greenhouse gas emissions. To reduce carbon emissions, nuclear power for electricity supply is a potentially important source. The fraction of world needs which can be supplied by nuclear will depend upon considerations such as the size of nuclear fuel reserves, the efficiency of old or even new generations of nuclear reactors when using lower grade uranium ores, and, more importantly, finding satisfactory solutions for nuclear waste disposal or storage. Fig. 1 plots the present world-wide energy consumption of oil, coal and natural gas and compared to nuclear, hydro and renewable energy technologies. The last convert the energy from different natural sources such as sun, tides, wind and others, into its usable forms such as electricity. Fig. 1 shows nuclear flattening out in and probably for the near future. On the other hand, the global renewable energy consumption increases significantly and its market is anticipated to grow rapidly during the forecast period owing to increased emissions of greenhouse gases (GHGs), particularly CO₂ due to utilization of fossil fuels for generation of energy. In addition, limited presence of fossil fuel on the earth as well its volatile prices fuels the renewable energy market. However, generation of energy from renewable sources requires huge investment. The global renewable energy market was valued at \$928.0 Billion in 2017, and is expected to reach \$1512.3 Billion by 2025, registering a growth rate of 6.1% from 2018 to 2025.

While all renewable energy sources need to be considered in meeting the energy challenge, solar energy, which includes biofuels, solar thermal energy, and photovoltaics (PVs), may arguably be the only renewable source capable of supplying a significant fraction of energy at predicted future levels. This is primarily because of the enormous energy resource represented by the sun which continuously floods the earth with 125,000 TW of power. This sector has only just begun to reveal its enormous potential for growth. Furthermore, the drop in solar photovoltaics (PVs) system prices allowed the investments to be used for installing 131 GW of PV panels in 2019, bringing the cumulative PV installation to 635 GW and thus capable of producing more than 585 TWh (terawatt hours). Yet, this represents only 2.2% of electricity share worldwide, but 3.9% in Europe.

Photovoltaics: Advanced Inorganic Materials

Based on IRENA report in June 2020, newly installed renewable power capacity increasingly costs less than the cheapest power generation options based on fossil fuels. Thus, more than half of the renewable capacity added in 2019 achieved lower electricity costs than new coal. New solar and wind projects are undercutting the cheapest of existing coal-fired plants. Indeed, solar and wind power costs have continued to fall, complementing the more mature bioenergy, geothermal and hydropower technologies. Fig. 2 shows that photovoltaic (PV) manufacturing was growing at approximately 30% per year since year 2000 and this rate is slightly decreasing due to economic crisis and industry consolidation (Fig. 2). It is worth reminding that the important growth has been the result of government policies (subsidies or feed-in tariff), mainly in Japan and in Germany. PV production was further stimulated by the goals for PVs set in, for instance, the EU White and Green Paper of 12% of the total energy and 22% of electricity generated by all renewable energies and 3 GWp in Europe for PVs in 2010. More recently, the EU seeks to have a 20% share of its gross final energy consumption from renewable sources by 2020. As a matter of fact, the growth in electricity from PV has been dramatic, rising from just 7.4 TWh in 2008 to 115.0 TWh in 2018. Similarly, the Solar America Initiative in the United States calls for investments to make PV power competitive with other forms of renewable energy and a growing number of states have mandated renewable energy standards. Overall, cumulative PV installation worldwide reached 635 GW in 2019 while it was 140 GW in 2013. The most rapid growth in annual production over the last 5 years has been observed in Asia, where China, Taiwan and Malaysia together now account for more than 80% of worldwide production (Fig. 2). The impressive progress is also due to the substantial technology improvements in materials quality, devices processing, fabrication and design, and also in characterizations. All these together led to better device performance and reliability, and lowered the systems costs. Electricity costs from utility-scale solar PV fell 13% year-on-year, reaching nearly seven cents (USD 0.068) per kilowatt-hour (kWh) in 2019.

Since 1980, most of the total PV modules shipments are based on single-crystal and multicrystalline silicon wafers (Fig. 3). This is typically referred to as the first generation of PVs. Fulfilling the projected demand for crystalline silicon based cells and modules will require innovative research and development to increase the efficiency and reduce the cost. Major activities directed toward such goals will be addressed below. Projections based on historical cost reduction trends has suggested that the price for conventional silicon solar cells will drop over years to a competitive level with fossil fuel. This is now the case in several parts of the world. The second PV generation based on inorganic semiconductor thin films has the potential for much lower costs and will also be addressed here. Finally, third generation PV concepts aimed at ultra-high efficiency and/or ultra-low cost regimes and involving nanotechnologies, multiple junctions, and bandgap engineering will be considered. These approaches are already on the laboratory research bench and in some instances (e.g., multijunction approaches) nearing market production. Prior to describing these materials and related technologies for PV conversion, a brief discussion of solar cell operation and key figures of merit will be presented.

PV Devices

A solar cell is a semiconductor device that converts photons from the sun into electricity. Fig. 4 shows the generic structure and operation of a single junction inorganic solar cell. At the heart of the cell is the light absorbing semiconductor material which converts photons into carriers (electrons and holes) via the PV effect. The different PV materials discussed in this chapter are identified by the composition and properties of the absorbing material (Slaoui and Reuben, 2007). After carrier generation, the electrons and holes separate and are collected at the contacts. There are two main modes for charge carrier separation: drift of carriers, driven by the built-in electrostatic field of a p–n junction, and diffusion of carriers from zones of high to low carrier concentration following an electrochemical potential gradient. When drift is important, the structure of the cell can be used to compensate for poor diffusion. When diffusion is used, then improvement in material quality becomes more of the focus. Drift is typical of thin film inorganic cells which are normally p–n junction devices which relatively high defect densities, while diffusion is more important for high efficiency single-crystal cells and is the driving transport mechanism for dye or organic solar cells. These later approaches have significant potential for low cost energy production but will not be discussed here. An in-depth review of organic PV technologies was recently published by Cao and Xue (Cao and Xue, 2014).

The properties of the contacts and window layers are also critical to device performance. At least one contact needs to be both electrically conducting and transparent to photons in the spectral range where the absorber creates carriers. Transparent conductive oxides are the material of choice for this purpose. It is also important to point out that the simple structure and the division into

Fig. 3 Distribution of cell production by technology in 2019. Data source: From 2000 to 2009: Navigant; from 2010: IHS Markit. Graph: PSE Project GmbH 2020.

Fig. 4 Schematic of the structure and of carrier generation and separation in a p-n junction solar cell. E_v is the valence band energy, E_f is the Fermi level, and E_c is the conduction band energy (with courtesy of Sarah Kurtz).

well-defined layers with specific functions shown in [Fig. 4](#) is not adequate to describe many solar cells. In a number of designs light enters through the substrate, and contacts can be quite complicated, fabricated from several layers and with significant inter-diffusion at metallurgical junctions.

Figures of Merit

Here we discuss some of the basic metrics for characterizing PV devices which are typically quoted by the industry and appear in the rest of this chapter. [Fig. 5](#) shows a typical current voltage (J-V) characteristic for a solar cell in the dark and under illumination. Power is generated when the cell operates in the fourth quadrant of the graph where voltage is positive and current is negative. The fill factor is the power produced at the maximum power point on the illuminated J-V curve divided by the product of the open circuit voltage (V_{oc}) and short circuit current (J_{sc}). We can think of it as a measure of how rectangular the JV characteristic is in the fourth quadrant. Another useful measure, quantum efficiency (QE), is the ratio of the number of charge carriers collected by the solar cell to the number of photons at a given illuminating energy. Ideally it is a step function at the bandgap of the absorber. In real devices, however, this is never the case and there is also a roll off at higher energies.

The most fundamental measure of performance is, of course, the energy conversion efficiency – the portion of energy in the form of sunlight that can be converted via photovoltaics into electricity by the solar cell to electrical energy. Two decades ago, Shockley and Queisser (S-Q) ([Shockley and Queisser, 1961](#)) used a detailed balance approach to estimate the thermodynamic efficiency limit for solar cells with a single absorbing material (a single junction design as shown in [Fig. 4](#)). Their approach balanced the radiative transfer between the sun, modeled as a black body at 6000K, and the solar cell assumed to be a 300K black body which absorbs photons with energy above an energy threshold (the band gap). They varied the band gap of the absorber and

Fig. 5 Current voltage (J–V) characteristics of a solar cell with and without illumination. The open circuit voltage (V_{oc}), short circuit current (J_{sc}), and fill factor are identified on the figure. Reproduced by permission of the MRS Bulletin.

the solid angle from which the solar cell can collect the sun radiation (concentration). As the band gap of the absorber increases, the open circuit voltage increases, but, because only photons with energy above the bandgap are converted into carriers, short circuit current decreases. This leads to a maximum in efficiency as a function of band gap. For unconcentrated solar irradiance, a maximum efficiency limit of $\sim 31\%$ at a gap near 1.3 eV was found. For full solar concentration (46,300 suns) maximum efficiency was $\sim 41\%$ for a 1.1 eV material. One limiting factor for higher efficiencies is that the excess kinetic energy of hot photogenerated carriers created by the absorption of supra-bandgap photons is lost as heat through phonon emission, and the other limiting factor is that photons less than the bandgap are not absorbed. Designs which attempt to increase cell efficiencies above the S–Q single junction limit by addressing one or both of these loss mechanisms are often termed third generation approaches in literature. Several are discussed below.

PV Materials

Crystalline Silicon

As stated above, most of the nowadays shipped PV modules are single-crystal, or multicrystalline based cells. Thus most efforts at the laboratory and industry scales went to the improvement of silicon based solar cells efficiency implementing innovative and low cost processes. Research and development in this area learned from silicon integrated circuits technologies and developed structures that maximizes the electron-hole generation and reduces surface and bulk recombinations. Thus, cells have reached laboratory performances converting nearly one-fourth of the incident photons into electrical power – reaching about 92% of its reported “theoretical limit”. To go further, more complicated designs and structures are sought. Among the advanced structures that allow cells reaching efficiencies over 22% on multicrystalline silicon and 24% on monocrystalline silicon (**Fig. 6**), there are single-sided and doubled-sided buried contacts (SSBC and DSBC), the metal/insulator/n-type/p-type (MINP), bifacial cells (BFC), the rear contact solar cells (RCC) and the heterojunction structure (HIT). The highest efficiency cells combine advanced structures such as RCC at the back and HIT at the front which allows to reach 26.7%. Detailed routes can be found in the recent proceedings of PV conferences.

Another important research activity dealing with silicon based cells is how to close the differences between the less perfect materials, namely multicrystalline silicon, and the single-crystal cell. The roles of defects and impurities – and their interactions and impacts on solar cell performance – remain important. Thus R&D still concerns understanding the nature of the defects resulting from the growth and processing and materials treatments to minimize the carrier losses at unwanted active sites ([Beaucarne and Slaoui, 2006](#)). These have included processes involving hydrogen, lithium, aluminum, arsenic, and phosphorus for front and back surfaces. The development of plasma and other nitriding processes by the semiconductor electronics industry has led to improvements in single and multicrystalline. Additionally, the economics of using less material has led the industry to investigate the production and use of thinner wafers, going from standard 300 μm thick wafers down to 100 μm . This however presents considerable difficulties in handling and processing because of mechanical fragility for these very thin wafers thickness and extremes in temperature cycling and thermal stresses they must endure during processing.

Among original thinned “wafer” technologies that have been investigated, there are Sliver® cells. The former one is composed of silicon strips that are produced by micro-machining narrow 100 μm deep grooves into a-Si wafer. These bifacial cells have had efficiencies up to about 18%, with prototype minimodules (560 cm^2 area) above 12% efficiency. The cells are being considered for transparent and concentrating modules, in addition conventional module use, but the reproducibility is a critical issue. A great effort was also deployed these last years to explore new technology without wire-sawing ([Slaoui et al., 2002](#)). Thus, several kerfless wafering techniques have been proposed: epitaxial Si lift-off, stress-induced spalling, and smart-cut. Using an epitaxial Si lift-off technique, a thin wafer is epitaxially grown on a porous seed Si wafer by atmospheric chemical deposition (APCVD) and exfoliated from the parent seed wafer. Epitaxial growth of high quality Si wafers, comparable to high performance CZ wafers, was

Fig. 6 Evolution of Solar Cell Efficiency since 1993 for different photovoltaic materials. Data: Green, M.A., Dunlop, E.D., Hohl-Ebinger, J., *et al.*, 2019. Solar cell efficiency tables (version 55). Progress in PV: Research and Applications. Graph: PSE Projects GmbH 2020.

demonstrated, and high efficiency above 21% based on a 35 μm thickness Si wafer was achieved. The stress-induced technique or SLIM-cut employs a stress induced layer on the Si wafer, and the stress is activated by thermal expansion mismatch between the stress layer and the Si wafer for spalling of thin wafers. Recently, a novel method of electrodeposit-assisted stripping (EAS) has been developed where a thin stress layer is electro-deposited at room temperature, and the lattice mismatch between the stress layer and the wafer induces a large stress field, which causes the lift-off of a thin Si wafer without high temperature annealing. Another kerfless wafering technique based on a smart cut technique invented in 1990s was attempted to fabricate thin wafers of tens of micrometer thickness for Si solar cells using a MeV proton implanter. The implanted protons are penetrated into a certain depth of the donor wafers depending on the proton acceleration energy. The implanted wafers are subsequently annealed to be exfoliated by hydrogen micro-bubble formation and crack propagation. The proton induced exfoliation technique is a relatively simple and clean vacuum process compared with the epitaxial Si lift-off method.

Thin Films

Thin-film PVs are attempting since several years to enter the world commercial markets (Fig. 3). Although their market share is still very small, the interest is driven in part by capacity problems with crystalline Si. The arguments favoring thin-film PV are based on low materials utilization, large-scale manufacturing advantages, and better energy economy for production and product recovery. Thin film technologies also enable other new and desirable properties for specialized applications (flexible modules, semi-transparent modules, etc.). In addition, research results with these systems have been very impressive with laboratory device efficiencies for some systems over 20%. Despite the very positive potential of these technologies, there is a strong need for intensive basic research to better understand fundamental properties of these materials and devices, especially of interfaces, low cost, high performance transparent conducting oxide (TCO) materials, new multijunction designs, alternative module concepts, and of methods for increasing device and module efficiencies. This section begins with a discussion of polycrystalline and amorphous silicon as well as the chalcogenide thin film cell technologies followed by TCO materials.

From amorphous to polycrystalline silicon films

Amorphous silicon (a-Si:H) is a very attractive material for large area thin film electronics, namely as thin film transistor for flat panel displays, as color sensors, or as absorbing layer for solar cells. The main advantages of this material is the low deposition temperature that offers the use of glass and flexible substrates, the potential of tuning the energy bandgap (1.7–1.9 eV), the facility of doping by adding dopant gases during film growth, and finally the possibility of stacking layers without severe constraints. Several physical or chemical deposition techniques are used to produce hydrogenated amorphous silicon such as magnetron evaporation, plasma enhanced CVD, and more recently very high frequency CVD. The main drawbacks when using such disordered material for solar cells are its low charge carrier mobility and diffusion length due to bond angle and bond length distortion, in addition to the strong sensitivity of the silicon-hydrogen bonds to the solar radiation. Consequently while higher open circuit voltages can be achieved on a-Si:H based solar cells, the photocurrent is limited by insufficient absorption of the solar spectrum and by high carriers recombination. Despite these limitations, single- and multijunction solar cells and large area modules based on a-Si:H and related alloys, e.g., a-Si_{1-x}Gex:H are now established on the market. The use of stacked multijunction cells (a-Si:H/a-Si:H/a-SiGe:H) led to high QE records. The a-SiGe:H layer is employed as a bottom cell because alloying the silicon with germanium conducts to narrower optical gap and therefore to broader optical absorption. To increase the

Fig. 7 A schematic structure of an amorphous (a-Si)/microcrystalline silicon ($\mu\text{c-Si:H}$) hybrid solar cell structure (with courtesy of E. Fortunato *et al.*).

efficiency further and reduce light-induced degradation of the cells, a combination of amorphous and microcrystalline silicon ($\mu\text{c-Si:H}$) is used nowadays (Fig. 7). The $\mu\text{c-Si:H}$ layer consists of an amorphous tissue with coherent regions of crystalline grains having sizes from nanometer scale to micrometer scale. The $\mu\text{c-Si:H}$ can be prepared at low temperatures by the same techniques as amorphous silicon and has absorption spectra similar to crystalline silicon. Furthermore, these materials contain several percent of hydrogen, thus remaining grain boundaries activity is neutralized.

As for the solar cells, by using a single junction cell with a homogenous microstructure, a stabilized efficiency of $\eta = 10\%$ on texture-etched ZnO:Al has been obtained. Reported stabilized efficiencies for a-Si/ $\mu\text{c-Si}$ tandem cells are approaching 12.5%. The highest confirmed efficiency for tandem submodules (Kaneka Co.) based on a-Si/ $\mu\text{c-Si}$ is 11.4%. For triple-bandgap a-Si/a-SiGe/ $\mu\text{c-Si:H}$ cells, a world record initial efficiency of 15% for thin film silicon PV technology has been obtained, using optical enhancement techniques, such as textured back reflectors and in some cases also intermediate selectively reflecting layers. Apart from the triple-bandgap a-Si/a-SiGe/ $\mu\text{c-Si:H}$ approach, the a-Si/ $\mu\text{c-Si}/\mu\text{c-Si}$ is also under investigation. United Solar Ovonic reported a stabilized efficiency of 13.3% for a-Si/ $\mu\text{c-Si}/\mu\text{c-Si}$ triple junction structures. There are still windows for further improvements by better controlling the interfaces and reducing defects in the layers.

As a natural extension of the trend toward higher crystallinity of the active layer, there is some effort in developing thin-film polycrystalline silicon. Such thin crystalline silicon films grown on various foreign substrates is formed by a variety of different methods that can be distinguished by the principle of the deposition process: chemical vapor deposition including the conventional high temperature CVD (APCVD, LPCVD), CVD on liquid layers (CVDOLL), plasma enhanced CVD (PECVD), the ion assisted deposition (IAD), the liquid phase epitaxy (LPE), and the solid phase crystallization of amorphous silicon (SPC), the aluminum induced crystallization (AIC), the laser induced crystallization (LIC). Except the LIC process, most of these methods result on polycrystalline silicon materials with fine grains ($< 10 \mu\text{m}$) and show relatively short minority carrier lifetimes compared to multi- or monocrystalline silicon material. Minority carrier diffusion lengths are usually in the range of only a few μm , smaller or comparable to the film thicknesses. The analysis of minority carrier properties of poly-Si films is intrinsically complicated by its inhomogeneous nature that results from the broad grain size distribution and potential fluctuations within individual grain boundaries. As a consequence, the open circuit voltage of such poly-Si thin film cell is quite small ($< 570 \text{ mV}$). The efforts toward reducing the barrier height and thus charge carrier recombination include the doping of the absorber layer, lowering the trap density at the grain boundary by strong hydrogenation and increasing the grain size.

An interesting approach towards a higher conversion efficiency is the HTJ that combines an absorbing large grains polysilicon layer formed by the AIC process, thickened by an absorbing Si film grown by CVD, and adding on top an emitter made of doped a-Si:H thin film. Such combination resulted so far in an efficiency approaching 10%. In order to be successful, thin-film polysilicon devices need to improve further and reach more than 16% module efficiency on superstrate configuration, with a process that is industrially applicable.

Thin-film CdTe, copper indium selenide, its alloys and related chalcopyrites

Polycrystalline thin film solar cells utilizing the II–VI semiconductor cadmium telluride and alloys of the I–III–VI materials, copper indium diselenide (CuInSe_2) and copper gallium diselenide (CuGaSe_2), are rapidly entering the marketplace. These materials have a number of interesting properties which make them attractive candidates for thin film PV technologies. Both CdTe and the Cu(InGa)Se_2 (CIGS) alloys are direct band gap compound semiconductors with energy gaps in the 1.1–1.6 eV range which are nearly ideal for single junction solar cell efficiency (Fig. 8). They have high optical absorption coefficients ($> 10^5 \text{ cm}^{-1}$) allowing for thin absorber layers. They are also more tolerant of defects than, for example, silicon and III–V compound semiconductors like GaAs. In spite of the high density of grain boundaries in the films, laboratory solar cells with record efficiencies of 21% (CdTe) and 23.4% (CIGS) have been reached (Fig. 6). There is even evidence that grain boundaries are beneficial, assisting carrier collection.

Fig. 8 CIGS (top) and CdTe (bottom) PV structures seen in cross-section using SEM (left side of panel) and viewed schematically (right side of panel) (with courtesy of E. Fortunato *et al.*).

Doping in these materials arises, in fact, from native defect formation during deposition and processing rather than introduction of substitutional impurities. This also means controlled doping and conductivity is one of the challenges in optimizing cells.

They also have similar cell structures. The junction itself is typically a heterointerface between n-type CdS and the p-type CIGS or CdTe absorber layer. Light enters through the CdS side of the device and current is carried away by a TCO film which is in contact with the CdS. Since CdS has a bandgap of 2.4 eV, it absorbs in the blue, however, photons absorbed in it produce little to no photocurrent. For this reason, both CdTe and CIGS cell processing seek to make the CdS layer as thin as possible while still remaining free of pinholes which create shorts between the TCO and absorber layers lowering V_{oc} and cell performance. This is especially problematic for CdTe cells where S diffusion into the CdTe during post growth anneals further decreases the CdS layer thickness. The inclusion of thin buffer layers between the TCO and CdS, such as a highly resistive transparent oxide, is found to improve efficiency. The exact role of the buffer layer, whether it simply introduces resistance into shorts or changes the interfacial energetics, is not well understood and optimizing this interface is an important area for materials innovation.

There are also some significant differences in the physical properties and processing of cells from CdTe and CIGS. The highest efficiency CdTe cells operate in a superstrate configuration with light entering through the glass on which the cell is grown. The record efficiency laboratory devices are prepared by high temperature absorber growth (near 600°C). Nearly all preparation schemes follow the CdTe growth with an anneal near 400°C in an atmosphere of CdCl₂ and oxygen that promotes grain regrowth, improves the CdTe carrier lifetime, diffuses the junction region, increases p-type conductivity in CdTe, and forms oxides. Back contacts to CdTe often involve Cu incorporation (e.g., Cu doped graphite paste or Cu doped ZnTe). The Cu diffuses rapidly through the device and may be a stability issue. An optimized back contact for CdTe devices, and better understanding of back contact/CdTe interfacial energetics, is a critical need.

In contrast, CIGS thin film cells are grown in a substrate configuration with the TCO contact as the last, rather than first, layer deposited. The highest efficiency CIGS cells are grown by physical vapor deposition and the grain microstructure is defined by a complex evolution from Cu rich to In and Ga rich phases during growth. Reproducing this growth path with other more manufacturable deposition options is a major challenge. In optimized devices, the Ga alloy composition is graded by 5% across

Fig. 9 An Organic solar cell structure (left); a Dye Sensitized Solar Cell structure (Middle); a Perovskite Solar Cell (right).

the absorber layer. Incorporation of Na ions, which occurs naturally as an aspect of growth on soda lime glass substrates, is also important to optimize the CIGS device efficiency. Although there is not a definitive explanation for the beneficial effects of Na, Na is believed to reduce the resistivity of the film. Typical absorber deposition temperatures are over 500°C for CIGS and a post-deposition anneal in a Se atmosphere is recommended. Decreasing deposition and post growth anneal thermal budgets for both CdTe and Cu(InGa)Se₂ are important cost reduction goals. The typical CIGS back contact is a molybdenum film. Device film adhesion issues are often traceable to issues with the molybdenum film. Cu(InGa)Se₂ devices where S is substituted for Se are also being explored allowing broader tunability of electronic properties and structural properties.

While reasonable stability under operation has been demonstrated for CdTe and CIGS solar cells, the performance of both can degrade in the presence of moisture. For this reason, they are encapsulated between glass sheets to seal the front and back surfaces of the modules, with polymer compounds sealing the edges and bonding the laminate together. Alternative polymer encapsulation schemes are also explored for CIGS devices. Finally, we note that issues of scarce elements (e.g., In) and toxicity (e.g., Cd) are frequently discussed in the context of both technologies. Whether or not either a truly significant issue depends at least in part upon feasibility, cost, and implementation of recycling and element recovery at end of product life. For example, First Solar, Inc., one of the rapidly growing CdTe panel manufacturers, includes panel recycling as part of product lifecycle management.

From organic to hybrid structures

In addition to crystalline-Si (c-Si) solar and inorganic thin film cells and modules, other thin film photovoltaic technologies – including organic solar cells (OSCs), dye-sensitized solar cells (DSSCs), and perovskite solar cells (PeSCs) – have gained attention for their many attractive properties, including low-cost, light weight, low fabrication temperatures, mechanical flexibility, and short energy payback times. In terms of their power conversion efficiencies (PCEs), they also exhibit respectable performance; the certificated PCEs of OSCs, DSSCs, and PeSCs have reached 13.5%, 14.3%, and 21.6%, respectively (Fig. 6).

Fig. 9(a) displays a typical device structure of an organic photovoltaic device (Chen *et al.*, 2014). The organic blend layer is sandwiched between two electrodes. The photoactive layer of the most common model device consists of poly(3-hexylthiophene) (P3HT) as the electron donor and phenyl-C₆₁-butyric acid methyl ester (PC₆₁BM) as the electron acceptor. Such materials are used because they possess different electron affinities and offset energy structures. The donors and acceptors are intermixed directly to maximize the interfacial area and this arrangement is often referred to as a “bulk heterojunction” (BHJ). After the absorption of photons by the organic semiconductors, excitons are generated. Because the binding energy of the excitons in organic semiconductors is usually high, they can be separated and turned into free charge carriers effectively after they have diffused to the donor-acceptor junctions. In such BHJ device, the high interfacial area leads to a high density of free charge carriers, due to efficient exciton dissociation at the donor-acceptor junctions. Finally, the photon generated holes and electrons are transported through the organic donor and acceptor semiconductors, respectively, to the corresponding electrodes, eventually resulting in a photocurrent. Present investigations concern the control of the morphology through various methods, such as thermal annealing, solvent annealing, and the use of processing cosolvents has been proposed for improving the device performances. Further, the development of low-bandgap (LBG) conjugated polymer donors, which allow them harvest photons with long wavelength from solar irradiations, also significantly improves the efficiency of OPVs. More recently, the efficiency of the OPVs prepared with

nonfullerene electron acceptors have reached a value of over 13%, thereby opening up new opportunities for even higher efficiencies approaching 18%.

As for the Dye Sensitized Solar Cell (DSSC) devices, Fig. 9(b) illustrates its working principle. This hybrid structure consists of a mesoporous TiO_2 working electrode (anode), a Pt counterelectrode (CE; cathode), and an electrolyte (e.g., an iodine-based redox mediator). When the device is illuminated, the sensitizer (dye) is photoexcited. The excited electrons in the LUMO are injected into the conduction band (CB) of TiO_2 , generating the oxidation state of the sensitizer (S^+). Meanwhile, the injected electrons on the CB of TiO_2 are transported to the transparent conducting substrate and then to the counter-electrode through the external electric circuit. The oxidized sensitizers are reduced by the redox couple I^-/I_3^- , thereby regenerating the ground state of the sensitizer (S). Simultaneously, the I^- ions are oxidized to I_3^- complexes and diffuse to the CE. Subsequently, the complexes are reduced to I^- ions at the CE, thereby completing the current circuit. There are also several competitive phenomena, which result in current loss, including recombination of the injected electrons with the HOMO of the dyes and/or with the I^-/I_3^- couple. Relaxation of the sensitizers to the ground states through a nonradiative decay process is another common loss path. Recent improvements in efficiencies of DSSC have been achieved by designing new dyes, such as zinc porphyrin dyes (YD2-o-C8). A recorded efficiency value of 14.30% was reported for a device prepared with metal-free organic co-sensitizers and with Co(II/III) -based redox electrolyte.

A strong alternative to the DSSC is the organic/inorganic hybrid perovskite structure. Fig. 9(c) displays a schematic of a typical perovskite solar cell. The perovskite absorbing material has the formula ABX_3 , where A, B, and X are ionic units. For organic/inorganic hybrid perovskites, A, B, and X are a large organic cation, a smaller metal cation (e.g., Pb^{2+} , Sn^{2+} , or Ge^{2+}), and a halide anion (I, Cl, or Br), respectively. Meanwhile, A and B are usually monovalent and divalent cations to fulfill charge neutrality. For instance, in the representative perovskite $\text{CH}_3\text{NH}_3\text{PbI}_3$, the A- and B-site cations are CH_3NH_3^+ and Pb^{2+} , respectively. At present, most high-performance perovskite solar cells (PeSCs) adopt an all-solid-state device configuration; For instance, the perovskite material is embedded between a mesoporous TiO_2 layer, which is permeated by the perovskite, and a high-work-function hole-transporting layer (HTL) – for example the spiro-MeOTAD. The TiO_2 layer is usually first deposited on a glass substrate precoated with a transparent conducting oxide (TCO). A high-work-function metal (e.g., gold) is deposited on the HTM. The working principle involves the perovskite layer absorbing the incident light, thereby exciting electrons and holes. These charges are extracted and transported by the TiO_2 layer and HTM, respectively, leading to a photocurrent. The continuous improvements in efficiencies of PeSCs involve many key factors, including the optimization of device structures, deposition conditions, composite manipulation and stability aspects. At the date of writing this document, a certified PCE of 25.2% has been reported, very close to that of the single crystalline solar cell record of 26.7%.

Transparent contact oxides based contacts chalcopyrites

TCOs become essential for many important components of PV devices ranging from crystalline Si heterojunction cells (HIT) to organic PV polymer solar cells (Figs. 6 and 9). They are used as electrode elements, structural templates, or diffusion barriers. They are essential to tune the open circuit device voltage by choosing the right work function. The suitable characteristics of the TCO materials include high optical transmissivity across a wide spectrum and low resistivity. Additionally, TCOs for terrestrial PV applications must use low cost materials and some may require device-technology specific properties.

The first TCO, namely CdO , was reported already in early 1990s and was both optically transparent and electrically conducting. Since then, three oxides have emerged as commercially important transparent conductors: (1) indium oxide, (2) tin oxide, and (3) zinc oxide. The properties and crystal chemistry of the transparent conducting indium oxide family of materials are very well documented nowadays since it is the highest performance, best understood material in the TCO class. By volume, however, the most deposited TCO today is SnO_2 which is used in IR-efficient architectural window applications. ZnO is also primarily currently used in window coatings but recent processing-related performance improvements and low cost makes it an attractive replacement for high-cost in-based TCOs.

Another possible choice of replacement of ITO electrode especially for large area high-efficiency cells is the use of optically transparent nanopatterned metal films. Indeed, it was recently discovered that metal films patterned with arrays of nanoscale holes transmit light with efficiencies much higher than expected from purely geometric considerations. The benefits are low sheet-resistance, withstanding larger deformations associated with substrate bending and substantial cost savings.

Multijunction Tandem Cells

The multijunction cell approach is most mature and most successful third generation technique for improving performance over a single junction cell. Here solar cells are stacked in order of their bandgap, with solar radiation entering the largest band gap cell first. Light is automatically filtered as it passes through the stack, with each cell absorbing a narrow energy range of above band gap photons thereby minimizing hot carrier losses. Below band gap photons are transmitted. Those with energies above the smallest band gap in the stack have a high probability of being absorbed minimizing below band gap losses. The result is a multi-junction solar cell with an ideal efficiency determined by the number of cells in series. The theoretical efficiency limit is 86.8% for an infinite number of band gap energies at very high concentration levels. If bandgaps are appropriately selected so that each cell in the stack generates nearly the same current, the cells can be interconnected in series making monolithic integration possible.

The most simple and common multijunction structure is the two junction thin film that utilizes a hydrogenated amorphous silicon (a-Si:H) upper junction (see discussion above) with a bandgap near 1.7 eV and second lower junction of microcrystalline silicon (μ c-Si:H) with a bandgap near 1.1 eV. This combination is almost ideal for a two-cell stack and boosts amorphous silicon stabilized cell efficiency from 9.5% for a single junction to better than 11% for the stack, under the one-sun air mass 1.5 (AM1.5G) spectrum condition. Triple junction designs which incorporate an additional amorphous layer, such as a: SiGe alloy, are beginning to enter manufacturing with stabilized efficiencies in excess of 13%. While this design represents a materials science tour de force, it is difficult to realize the full benefit of multiple junctions when the solar cells are made from polycrystalline or amorphous materials with lower crystal perfection.

Maximizing device efficiency requires long minority carrier lifetimes and, hence, high materials quality. Crystalline group IV (Si and Ge) and III–V compound semiconductors (GaAs, InP, and the numerous III–V alloys) are the best candidates for multi-junction cells. The III–V materials, in particular, are ideal for fabricating such MTJ solar cells for two reasons: they can be grown with excellent material quality using techniques such as molecular beam epitaxy and organometallic chemical vapor deposition and their band gaps span a wide spectral range (typically between 0.4 and 2.4 eV), mostly with direct bandgaps, implying high absorption coefficients. When fabricating these alloys, there are a number of possible ways to mix the endpoint compounds, even within a single-crystal layer, to tailor the optical or electrical properties. In general, lattice-matched materials are the easiest to manufacture with high quality. The lattice-matched nature of the $\text{Ga}_{0.5}\text{In}_{0.5}\text{P}/\text{Ga}_{0.99}\text{In}_{0.01}\text{As}/\text{Ge}$ cell is one of the reasons for its strong success. There has been success, however, with lattice mismatched structures, which increases the range of materials/band gap combinations which can be considered in optimizing a cell design. Perhaps the most exciting aspect of III–V multi-junction cell development is the broad range of phase space yet to explore in optimizing cell designs. It is known, for example, that the currents in the triple junction $\text{Ga}_{0.5}\text{In}_{0.5}\text{P}/\text{Ga}_{0.99}\text{In}_{0.01}\text{As}/\text{Ge}$ device are not optimally matched, and insertion of an additional junction with a 1.0 eV band gap directly above the Ge junction would improve efficiency. A GaInAsN alloy which has the desired band gap and is lattice matched has been studied extensively for this application but, so far, cannot be integrated with the required materials quality.

Modern preparation techniques such as wafer bonding to mitigate the effects of lattice mismatch has been also explored. World record for a monolithic triple-junction solar cell manufactured by wafer bonding has been increased to 34.1% and an efficiency record of 24.3% achieved for a solar cell with the III-V semiconductor layers deposited directly on the silicon. In this structure, the different layers absorb light from different spectral ranges: gallium indium phosphide (GaInP) in the 300–660 nm range (visible light), aluminum gallium arsenide (AlGaAs) in the 600–840 nm range (near infrared light) and silicon in the 800–1200 nm range (long-wavelength light). Recent research utilized GaInP/GaAs//GaInAsP/GaInAs as four junction solar cell (4JSC) and demonstrated a very high efficiency of 46% thanks also to the wafer bonding. The development of solar cells with more than four junctions is still in its very beginning. Nevertheless, the highest efficiency ever achieved up to end of 2019 has been obtained with a AlGaInP/AlGaAs/GaAs/GaInAs/GaInAs/GaInAs six junction solar cell.

The efficiencies already achieved with crystalline multijunction cells are truly astounding, and it seems likely that values near 50% are not that far off. These cells, however, were originally developed for space applications where power to weight ratio is the key figure of merit and they are too costly for flat plate terrestrial power production. Integration of the cells with lower cost solar concentrator designs, however, has the potential for enabling cost competitive systems. While concentrator designs are not being covered here, their development and improvement is equally (or perhaps more) important than improvements in cell efficiency to continuous cost reductions in PV systems based on high efficiency multijunction cells.

Emerging Materials and Cells Concepts

To overcome the S–Q efficiency limit mentioned above, there are preliminary reports and experiments on advanced exciting cell concepts which include several nanotechnology and hot-electron approaches such as the quantum dot (QD) cell and relatives using quantum rods and quantum pods. There are several approaches based on semiconductor QDs that could lead to ultra-high efficiencies through enhanced photocurrent. Among them:

Multiple exciton generation (MEG)

The formation of multiple excitons from a single absorbed photon occurs when the energy of the photon absorbed is greater than the semiconductor bandgap (Klimov *et al.*, 2007). Such process is well known in bulk semiconductors and is termed impact ionization (I.I.); it is the inverse of the Auger process whereby two electron-hole pairs recombine to produce a single highly energetic electron-hole pair. However, the probability that such phenomenon happens in bulk semiconductor is very low because the excess energy simply dissipates away as heat before it can cause other electron-hole pairs to form. But in semiconductor QDs, the rate of energy dissipation is significantly reduced, and the charge carriers are confined within a small volume, thereby increasing their interactions enhancing the probability for multiple excitons (MEG) to form (see Fig. 10). Theoretical considerations have reported a thermodynamic limit of about 45%. Quite recently very efficient MEG has been reported for PbSe, PbS, and PbTe QDs. Up to three excitons/photon have been measured in 2.9 nm diameter PbSe QDs when the energy of the photon absorbed is four times that of the bandgap, and up to seven excitons/photon have been reported for excitation at eight times the bandgap. More importantly, MEG has been reported for silicon QDs that might open larger opportunities for applications of such phenomenon in solar cells. These observations of MEG have effectively occurred in isolated QDs. The enhanced photocurrent

Fig. 11 Structure of an intermediate band material also showing the possible optical transitions (with courtesy of A. Marti).

possible with MEG has not been observed, to date, in a solar cell structure. The issue is one of finding a device design which incorporates QDs or wires and can directly collect the carriers generated within the nanostructure. Several configurations have been proposed including imbedding the QDs in polymers, imbedding them in other semiconductors, applying dots in place of the dye in a dye-sensitized solar cell design, and formation of QD solids from an assembled array of dots. Developing device designs that exhibit and ultimately take advantage of MEG to increase cell efficiency is presently an extremely active area of research.

Intermediate band approach

In this approach, QDs of binary or ternary semiconductors are used to create an intermediate band (IB) that allows the harvesting of a much larger portion of the available solar spectrum. Because of the IB, below bandgap energy photons can contribute to the cell photocurrent by pumping electrons from the valence band (VB) to the IB and from the IB to the CB (Fig. 11). But most importantly, since the IB is isolated from the CB and the VB by a zero density of states, "carrier relaxation" between bands becomes difficult and the carrier statistics in each band is described by its own quasi-Fermi level. The energy states of the QDs forming the intermediate bandgap can be controlled by the size of the dot. It can be shown that, under this assumption, the voltage supplied by the cell, given by the electron and hole quasi-Fermi level split, is still limited by the high bandgap E_G and not by any of the lower bandgaps (E_L or E_H). The study of the limiting PV conversion efficiency of the IB approach reveals a limiting efficiency of 47% at one sun (63% at full solar concentration) for this concept as compared to 43% for a two-gap tandem solar cell at one sun (55% for full solar concentration).

Several groups have been investigating QD-IB structures, but no devices using this approach have yet been validated. Among them prototype cells consists of 10 layers of InAs/GaAs QDs sandwiched by p and n GaAs emitters and grown by molecular beam epitaxy MBE in the Stranski-Krastanov growth mode. Such structures still suffer from poor absorption in the QDs and low open circuit voltage due to structural defects induced during the growth.

Another approach considers the use of Nitrogen in III-V or Oxygen in ZnMnTe to form an IB. For the latest, it is reported that the location and the width of the IB is determined by the O content. Calculations based on the detailed model predict maximum

Fig. 12 Schematic view of a two-cell “all silicon” tandem cell using silicon quantum dots embedded in SiO_2 , or SiN or SiC matrix (with the courtesy of G. Conibeer, UNSW).

efficiency of more than 55% in alloys with 2% of O. Additional investigations look to epitaxial techniques to grow ZnOxSe_{1-x} materials.

All-silicon tandem cells approach

As mentioned above the tandem cell concept is well established as a way of improving solar cell performance. Obviously there is a strong interest in implementing tandem cells based entirely on silicon thanks to the advantages of the QDs. Indeed, the first advantage of the QDs is their tunable bandgap. It means that the wavelength at which they will absorb or emit radiation can be adjusted: the larger the size, the longer the wavelength of light absorbed, and the greater the output voltage. On the other hand, a lower bandgap results in the capture of more photons including those in the red end of the solar spectrum, resulting in a higher output current but a lower output voltage. Thus, the highest solar-electric energy conversion can be theoretically achieved by using a superlattice based on a mixture of QDs of different sizes for harvesting the maximum proportion of the incident light effectively. Ideally such superlattices can then be used as the higher bandgap cells in a tandem stack. When applied to silicon (Fig. 12), the efficiency limit is found to reach 42.5% and 47.5% for two-cell and three-cell “all-silicon” stacks, compared to 29% for a single silicon cell considering only radiative and Auger recombination.

To successfully implement the all-silicon tandem concept, the following features need to be demonstrated: control of dot size and therefore bandgap, enhanced optical strength, adequate transport, P–I–N junctions (high V_{oc}), doping, work function control, and interconnected cells. Thanks to the development of nanotechnologies, control of QD size, and density in oxide, nitride, and carbide matrices has been demonstrated as witnessed by high-resolution TEM observations and photoluminescence measurements. However, obtaining the required charge transport properties in such systems are still under investigations in many research institutes, and might need some years of studies.

This is a reprint of J Kawamura, Ion Conducting Materials: Superionic Conductors and Solid-State Ionics, In: Reference Module in Materials Science and Materials Engineering, Elsevier Inc., 2016, doi:10.1016/B978-0-12-803581-8.01724-0.

Electrical conduction of solid is mostly by electrons or holes as in the case of metals and semiconductors. However, some special types of solids show ionic conduction, the conductivity values of which are often as high as those of aqueous electrolyte solutions. Although, the ionic conduction in solids was already known by Michael Faraday in 19th century (Funke, 2013), it is noticed very useful for applications after 1970: for example, for gas sensors, lithium ion batteries, fuel cells etc. They have been called *solid electrolytes* or *superionic conductors* now; the latter is used especially for those have unusually high ionic conductivity. Faraday found silver ion conduction in Ag_2S , which has also electron conduction together. These materials are now called *Mixed Ionic-Electronic Conductors (MIEC)*, which are inevitable for electrode materials of battery and fuel cell. Growing research on ionic transport in solids and its application after 1970, a technical term of *solid-state ionics* has been established, which refers to the science and technology of ions in motion in solids. International journals of "Solid State Ionics" and "Ionics" have been published, where new materials, applications and fundamental studies have been reported.

Classification of Solids With Ionic Conduction

Ionic conduction in solid was first observed in inorganic crystals like $\alpha\text{-AgI}$, PbF_2 etc., it is now recognized in many varieties of material. Morphologies of ion conducting solids can be classified into crystalline, amorphous (or glassy), and organic polymer materials. Nano-, micro-composite materials are also studied recent years. The ionic species of conduction (mobile ions) also spread from Ag^+ , Cu^+ , F^- to include Li^+ , Na^+ , H^+ , O^{2-} etc.; even Mg^{2+} or higher valence cations are also reported mobile in some solids.

Typical ion conducting solids are listed in Tables 1 and 2 with their conductivity and mobile ions. The temperature dependence of conductivity for representative solid electrolytes is shown in Fig. 1.

Fast mobile ions in solids are limited to some monovalent cations like Ag^+ , Cu^+ , Li^+ , Na^+ , and H^+ , which have rather small ion radius comparing to the surrounding anions. Higher valent cations despite their small ion size are so strongly bound to the surrounding anions that it is difficult to move easily in solids. In spite of this, some challenges have been reported on Mg^{2+} , Ce^{2+} , Sc^{3+} conductors as shown in Table 1.

Table 1 Typical ion conducting solids (crystalline solids)

Mobile ion	Composition	Conductivity (S cm^{-1})	Note
Ag^+	RbAg_4I_5	2.7×10^{-1} (25°C)	
	$\text{Ag}_6\text{I}_4\text{WO}_4$	4.7×10^{-2} (25°C)	
Cu^+	$7\text{CuBr} \cdot \text{C}_6\text{H}_{12}\text{N}_4\text{CH}_2\text{Br}$	2.1×10^{-2} (20°C)	
	$\text{RbCu}_4\text{Cl}_3\text{I}_2$	3.4×10^{-1} (25°C)	
H^+	$\text{H}_3\text{PW}_{12}\text{O}_{40} \cdot 29\text{H}_2\text{O}$	2.0×10^{-1} (25°C)	
	CsHSO_4	8×10^{-3} (160°C)	Superprotonic
	$\text{SrCe}_{0.95}\text{Yb}_{0.05}\text{O}_{3-\delta}$	2×10^{-2} (1000°C)	
Li^+	Li_3N	3×10^{-3} (25°C)	
	$\text{La}_{0.25}\text{Li}_{0.18}\text{TiO}_3$	1×10^{-3} (25°C)	LLT
	$\text{Li}_{14}\text{Zn}(\text{GeO}_4)_4$	1.3×10^{-1} (300°C)	LISICON
	$\text{Li}_{10}\text{GeP}_2\text{S}_{12}$	1.2×10^{-3} (25°C)	Thio-LISICON
	$\text{Li}_2(\text{BH}_4)(\text{NH}_2)$	2×10^{-4} (25°C)	Hydride
Na^+	$\text{Na}_2\text{O} \cdot 11\text{Al}_2\text{O}_3$	2×10^{-1} (300°C)	β -Alumina
	$\text{Na}_3\text{Zr}_2\text{Si}_2\text{PO}_{12}$	3×10^{-1} (300)	NASICON
K^+	$\text{K}_2\text{O} \cdot 5.2\text{Fe}_2\text{O}_3 \cdot 0.8\text{ZnO}$	1.8×10^{-2} (300)	
Mg^{2+}	$\text{MgZr}_4(\text{PO}_4)_6$	3×10^{-3} (800)	
Sc^{3+}	$\text{Sc}_2(\text{WO}_4)_3$	2×10^{-5} (600°C)	
F^-	PbF_2 (+ 2%KF)	2×10^{-2} (200°C)	
	$\text{Bi}_{0.9}\text{K}_{0.1}\text{F}_{2.8}$	7×10^{-4} (25°C)	
Cl^-	PbCl_2 (+ 3% KCl)	3×10^{-3} (300°C)	
	SnCl_2	2×10^{-2} (200°C)	
O^{2-}	$(\text{ZrO}_2)_{0.9}(\text{Y}_2\text{O}_3)_{0.1}$	2.0×10^{-2} (800°C)	
	$(\text{Bi}_2\text{O}_3)_{0.75}(\text{Y}_2\text{O}_3)_{0.25}$	8×10^{-2} (600°C)	
	$\text{La}_{0.9}\text{Sr}_{0.1}\text{Ga}_{0.8}\text{Mg}_{0.115}\text{Co}_{0.085}\text{O}_3$	6×10^{-2} (600°C)	

Table 2 Typical ion conducting solids (glass, glass ceramics, polymer, composite)

Mobile ion	Composition	Conductivity ($S\text{ cm}^{-1}$)	Note
Ag^+	$60\text{AgI} \cdot 40\text{Ag}_2\text{MoO}_4$	2×10^{-2} (25°C)	Glass
	$\text{AgI} \cdot \text{Al}_2\text{O}_3\text{PVA}$ etc.	$10^{-3} \sim 10^{-2}$ (25°C)	Nano-particle
Cu^+	$50\text{CuI} \cdot 50\text{CuPO}_3$	1.5×10^{-3} (25°C)	Glass
Li^+	$37\text{Li}_2\text{S} \cdot 18\text{P}_2\text{S}_5 \cdot 45\text{LiI}$	10^{-3} (25°C)	Glass

	$\text{PEO} \cdot \text{LiClO}_4$	1×10^{-5} (25°C)	Polymer
	$\text{Li}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot \text{TiO}_2 \cdot \text{P}_2\text{O}_5$	1.3×10^{-3} (25°C)	Glass ceramics
H^+	$\text{ZrO}_2 \cdot 3(\text{PO}_{2.5}) + x\text{H}_2\text{O}$	1×10^{-2} (25°C)	Sol-gel glass
F^-	$(\text{InF}_3)_{0.35}(\text{SnF}_2)_{0.2}(\text{PbF}_2)_{0.35}$	8×10^{-4} (150°C)	Glass

Abbreviation: PEO, polyethylene oxide.

**Fig. 1** Conductivity of ion conducting solids. S.C. single crystals, P.C. poly crystal.

As anions are, in general, larger in size than cations, their mobility is lower than that of cations. However, comparatively small size anions such as F^- and O^{2-} are mobile in some solids. In particular, F^- ions in Bi–Pb–In–Sn compounds or glasses are very mobile even near the room temperature. O^{2-} conductors are mostly used at high temperatures above 500°C for sensors or fuel cells. In particular a series of stabilized zirconia is a stable good O^{2-} conductor and is very important for practical uses.

Mechanism of Ionic Conduction in Solids

Fundamental Migration Mechanism of Ions in Solid

There are many types of conduction mechanisms depending on the crystal or non-crystal structure of the solid electrolytes. In a broad way, they are classified into two categories; Type A: sub-lattice liquid type, Type B: point-defect type.

(a) Type A: Sub-lattice liquid type

Most surprising ionic conductors are in this category, whose conductivity is more than 10^{-3} to 10 S cm^{-1} , which is the same order of liquid electrolytes or molten salts. So-called “superionic conductors” are in this category. A typical example is the high temperature phase of silver iodide ($\alpha\text{-AgI}$) which is stable above 147°C to the melting temperature 550°C . The ionic conductivity of $\alpha\text{-AgI}$ is 10 S cm^{-1} at 500°C , which is *higher* than its liquid state. The entropy change ΔS_t of the $\beta\text{-}\alpha$ transition at 147°C is

Fig. 2 Stock model of α -AgI structure.

$14.5 \text{ JK}^{-1} \text{ mol}^{-1}$ which is larger than the value $\Delta S_f 11.3 \text{ JK}^{-1} \text{ mol}^{-1}$ at the melting temperature of 550°C ; this means a half of the component ions (Ag^+) is fused at β - α transition and the remaining half (I^-) melts at normal melting point. This is similar to the case of liquid crystal or plastic crystals, which is categorized to a “meso-phase” in between solid and liquid.

Actually, detailed structure analysis of the type A crystals confirmed this concept. In case of the α -AgI, the iodide ions construct a fixed bcc. sublattice, where the silver ions are distributing and migrating randomly among them. A simple picture is shown in **Fig. 2**, where the two I^- locate at the center and the corners of bcc lattice, while the two Ag^+ are distributing in 42 sites in a unit cell. Moreover, detailed analysis of neutron scattering revealed the silver ions are traveling among these positions very fast like in liquid. Thus, the type A ionic conductor can be regarded as a meso-phase between liquid and solid. Similar sublattice liquid state is observed in fluoride structured F^- conductor PbF_2 , whose conductivity is also 1 S cm^{-1} at 900K as shown in **Fig. 3**. It is regarded as a superionic phase like α -AgI, although the transition to the superionic state is a continuous second order type (Faraday transition), which is different from first order transition of β to α -AgI (Catlow, 1989).

α -AgI or PbF_2 is an example of three dimensional (3D) ionic conductor, where the mobile ions can move any directions through the 3D conduction channels. 2D and 1D ionic conductors are also known. A typical example is sodium ion conduction in Na β -alumina ($\text{Na}_2\text{O} \cdot 11\text{Al}_2\text{O}_3$), which has a layered structure as shown in **Fig. 4**. The crystal framework is formed by spinel block layers composed of aluminum and oxygen. Na^+ ions (large gray circles) are distributing in a plane between the two spinel layers which are supported by the pillars of oxygen (double circles).

The array of Na^+ ions in the plane is ideally ortho-triangle, however the midpoint between oxygen-pillars (called *mid-oxygen site*; small circles in **Fig. 5**) are also energetically available. Therefore, Na^+ ions can easily move from their normal sites to the mid-oxygen sites and vice versa, which give rise to the liquid-like high Na^+ ion conduction. In comparison to the above mentioned AgI or PbF_2 which have 1st or 2nd order phase transitions to low temperature insulator phases, Na β -alumina shows no clear phase transition even below 10K , whose conductivity decreases linearly in Arrhenius plot; so that some authors (Boyce and Huberman, 1979) categorize AgI as type I, PbF_2 to type II and Na β -alumina to type III.

One dimensional or quasi-1D ionic conduction is often found in tunnel structured compounds. An example is a ramsdellite-type Li_2TiO_3 , in which Li^+ ions migrate through a tunnel surrounded by octahedra and tetrahedra of TiO_n . Some hollandite-type crystals as $\text{K}_{2x}\text{Mg}_x\text{Ti}_{8-x}\text{O}_{16}$ has also one dimensional tunnels surrounded by TiO_n . The potassium ions K^+ are distributing and moving freely in the tunnels, which give rise to the very high conductivity of 10 S cm^{-1} at microwave frequency. However, the conductivity at low frequency or dc region becomes very low probably due to some blocking impurities or defects in the tunnels.

When the tunnels of different directions are connected with each other, the macroscopic ionic conduction becomes 3D. The Na superionic conductor (NASICON) family represented as $\text{Na}_{1+x}\text{Zr}_2\text{Si}_x\text{P}_{3-x}\text{O}_{12}$ ($x < 2$) is a typical example (see Section on Sodium Ion Conductors).

It is necessary to mention briefly the structure and conduction mechanism of amorphous ionic conductors such as AgI- Ag_2MoO_4 glass or solid polymer electrolytes as PEO- LiClO_4 shown in **Table 2** (Junichi Kawamura *et al.*, 2006). Although these

Fig. 3 Ionic conductivity of AgI, PbF₂ and NaCl, from Hull, 2004.

Fig. 4 Structure of Hollandite type one dimensional K⁺ conductor (Yoshikado *et al.*, 1982).

materials have no long-range order like crystals, they have some short (~ 1 nm) and intermediate (~ 10 nm) range orders. In case of AgI-Ag₂MoO₄ glass, the glass is locally composed of AgI₄ and MoO₄ units connected randomly. The silver ions are mainly moving through the AgI rich regions like in the α -AgI, which link to form random conduction channels. In lower temperatures, some silver ions are trapped by the oxide ions resulting to the decrease in conductivity. No thermodynamic phase transition is seen, but the glass transitions are observed between the melt and the superionic glass as well as between the superionic glass and insulator glass. In case of the polymer electrolyte as PEO-LiClO₄, the lithium ion is trapped in a cage made of coordinating four oxygens in polyethyleneoxide network, whose micro Brownian motion allows the lithium ion to migrate from one cage to the other like transferring an apple through many baskets by bucket brigade manner.

(b) Type B: Point-defect type

Any ionic crystal has in principle some extent of ionic conductivity due to the intrinsic lattice defects in the crystal. Typical examples are so called Frenkel and Schottky defects created by the thermal energy at a temperature. Frenkel defect is a pair of

Fig. 5 Layer structure of β alumina. (a) Outward appearance, (b) cross-sectional plane perpendicular to layer, (c) arrangement of Na^+ between layers.

interstitial cation M_i and cation vacancy V'_M , whereas the Shottky defect is a pair of cation vacancy V'_M and anion vacancy V'_x as shown in Fig. 6.

Number density of the defects n can be expressed by defect equilibrium; for example, in case of Frenkel defects as,

$$n(T) = \sqrt{NN'} \exp\left(\frac{-G_F}{2kT}\right) \quad (1)$$

where N and N' are the number of normal sites and interstitial sites respectively. ΔG_F is the formation free energy of a Frenkel defect pair, k is the Boltzmann constant, T is the absolute temperature. Thus, the intrinsic defect density is determined by the defect formation free energy ΔG_F . On the other hand, extrinsic defects can be artificially created by heterovalent doping, for example, the doping of MgCl_2 to NaCl creates sodium vacancy V'_{Na} . The concentration of the extrinsic defects can be calculated by defect equilibrium theory (Kroger, 1964).

Once some defects are created in a crystal, they can migrate rather easily in the solid. There are fundamentally three ways of ionic transport by lattice defects; (1) vacancy mechanism, (2) interstitial mechanism, and (3) interstitialcy mechanism which are illustrated schematically in Fig. 7.

Small cations can migrate by both interstitial and vacancy mechanisms, although the large anions diffuse mostly by anion vacancy process. A typical example is the oxide-ionic conduction in stabilized zirconias such as $(\text{ZrO}_2)_{0.9}(\text{Y}_2\text{O}_3)_{0.1}$ (see Section on Oxide Ion Conductors), where an O^{2-} ion hops from its normal site to an adjacent anion vacancy V_{O} leaving a new vacancy behind. Another example is the fluoride-ionic conduction in fluorite-type solid solutions composed of $\text{Ca}_{1-x}\text{Na}_x\text{F}_{2-x}$ ($x \leq 0.05$), in which a monovalent sodium replaces a divalent calcium in CaF_2 to create a fluoride ion vacancy. In these materials, the vacant sites of movable ions are rather limited, for example, in the above described stabilized zirconia the number of oxide-ion vacancies is only 5% of normal anion sites. Thus, the ionic conductivity of the defect type solid is not so high as that of type 1 superionic conductors.

Fig. 6 Schematic model of (a) Schottky defect and (b) Frenkel defect.

Fig. 7 Typical ion transport mechanisms in point defect type ionic conductor; (1) vacancy mechanism, (2) interstitial mechanism and (3) interstitialcy mechanism.

Theory of Ionic Conduction in Solids

When the carrier density n is known, the ionic conductivity σ can be estimated by the following Nernst formula as,

$$\sigma = zen\mu \quad (2)$$

where μ is the mobility of the mobile ions; z and e represent their ionic valence and elementary charge, respectively. In case of Type A superionic conductors, the carrier density n is equal to the total mobile ions; for example, all Ag^+ in $\alpha\text{-AgI}$. In the case of Type B defect type solid, n is the number of the mobile defects expressed like Eq. (1). For vacancy mechanism, the charge carriers are regarded as vacancies instead of mobile ions themselves, thus the n should be the number of the vacancies.

The mobility μ in Eq. (2) is related to the diffusion coefficient D of the mobile ion by,

$$\mu = zeD/kT \quad (3)$$

Thus the ionic conductivity σ is expressed as the following Nernst–Einstein equation:

$$\sigma = (ze)^2 nD/kT \quad (4)$$

The diffusion coefficient of an ion in solid is well described by “jump model”; a mobile ion located in a bottom of a potential well with thermal vibration ν_0 attempt frequency overcomes a potential barrier ΔG_m in order to move to another site as shown in Fig. 7. Then the transition rate $\nu(T)$ is expressed as,

$$\nu(T) = \nu_0 \exp\left(\frac{-\Delta G_m}{kT}\right) \quad (5)$$

Table 3 Diffusion coefficients D_σ and D_{Tr} for several solid electrolytes

Material	Mobile ion	Temperature ($^{\circ}\text{C}$)	D_σ ($\text{cm}^2 \text{s}^{-1}$)	D_{Tr} ($\text{cm}^2 \text{s}^{-1}$)
$(\text{ZrO}_2)_{0.85}(\text{CaO})_{0.15}$	O^{2-}	1000	4.2×10^{-8}	4.2×10^{-8}
$\alpha\text{-AgI}$	Ag^+	200	2.53×10^{-5}	1.76×10^{-5}
$\alpha\text{-RbAg}_4\text{I}_5$	Ag^+	25	3.68×10^{-5}	1.75×10^{-5}
Sodium β -alumina	Na^+	25	6.8×10^{-7}	4.0×10^{-7}
Potassium β -alumina	K^+	25	3.17×10^{-9}	9.6×10^{-10}
Silver β -alumina	Ag^+	25	3.1×10^{-7}	1.7×10^{-7}
$\text{H}_3\text{PW}_{12}\text{O}_{40} \cdot 29\text{H}_2\text{O}$	H^+	27	4.5×10^{-6}	

Abbreviations: D_{comp} , component diffusion coefficient; D_{Tr} , tracer diffusion coefficient.

and the diffusion coefficient D is expressed as,

$$D = \frac{1}{6} v a^2 \quad (6)$$

where a is the jump distance shown in Fig. 7.

Thus, the ionic conductivity is expressed as,

$$\sigma(T) = \frac{(z_i e)^2 a^2 v_0}{kT} n_i \exp\left(\frac{-\Delta G_m}{kT}\right) \quad (7)$$

In case of Type A superionic conductors, since the n_i is almost independent of temperature the slope of $\log \sigma T$ vs. $1/T$, which is usually called *activation energy* gives the estimation of the barrier height.

On the other hand, in case of Type B defect type ionic conductors, the n_i strongly depends on the temperature as given in Eq. (1) for intrinsic Frenkel defect case. In this case the ionic conductivity is expressed as,

$$\sigma(T) = \frac{(z_i e)^2 a^2 v_0}{kT} \sqrt{N N'} \exp\left(\frac{-\Delta G_m + \Delta G_F/2}{kT}\right) \quad (8)$$

So, the apparent activation energy gives the sum of the defect formation and migration energies. The estimation of these energy values is a key subject of the solid state ionics, which are tabulated in some literatures (Kroger, 1964). One can say, the Type A superionic conductor is a limit of Type B with negligible value of ΔG_F .

It is worthwhile to compare the diffusion coefficient D_σ from conductivity experiment with the values from other experiments such as a tracer diffusion coefficient D_{Tr} by radio isotope experiment, or pulse-field gradient NMR technique D_{NMR} etc. An example is given in Table 3, where the value estimated from the conductivity by Eq. (4) is expressed by D_σ . Fairly good agreement is seen between D_{comp} and D_{Tr} , however small difference is also seen. The ratio of them is called Haven ratio HR or correlation factor f , which is an index of many-body effect and/or backward correlations of mobile ions.

The diffusion phenomenon that changes the chemical composition of the solid is called *chemical diffusion* and its coefficient is named the *chemical diffusion coefficient* (D_{chem}). In mixed conductors (see Section on Mixed Ionic-Electronic Conductors) such as $\text{Ag}_{2+\delta}\text{S}$ the diffusion of Ag^+ from the outside is accompanied by the diffusion of excess electrons changing the composition of the solid. The D_{chem} value of $\text{Ag}_{2+\delta}\text{S}$ at 200°C is evaluated to $0.1\text{--}0.3 \text{ cm}^2 \text{s}^{-1}$ and that of $\text{Ag}_{2+\delta}\text{S}$ is $0.5\text{--}1.5 \text{ cm}^2 \text{s}^{-1}$ depending on the composition. The chemical diffusion coefficient is now very useful to analyze electrode reactions in lithium ion batteries, SOFC etc.

Typical Examples of Ionic Conductor

Silver and Copper Ion Conductors

As is already explained above, the best-known example is $\alpha\text{-AgI}$, which has a sublattice melting superionic conductor state above 147°C ; below this temperature, it transforms into a β (wurtzite) or γ (zincblend) phase of poor conductivity as shown in Fig. 2. Many attempts have been made to stabilize the high conductivity $\alpha\text{-AgI}$ phase down to the lower temperatures, for example, by substituting other cations M for silver or substituting other anions X for iodide ions. Table 4 shows some room temperature-type silver ion conductors thus synthesized. Of these, RbAg_4I_5 has the highest conductivity of $2.7 \times 10^{-1} \text{ S cm}^{-1}$ at room temperature.

Similar to $\alpha\text{-AgI}$, the high temperature crystal form of CuI is an average structure with high Cu^+ conductivity. Similar attempts were made to stabilize the superionic phase to room temperature. Copper ion conductors thus synthesized are listed in Table 1.

Among these, $\text{Rb}_4\text{Cu}_{16}\text{Cl}_{13}\text{I}_7$ exhibits the highest conductivity, $4.7 \times 10^{-1} \text{ S cm}^{-1}$ at room temperature; this value is the highest one not only among the Cu^+ -conductors but also among all kind of solid electrolytes ever known.

Some other attempts have been made to stabilize the high temperature superionic phase to room temperature; (1) by glass formation with other oxides etc., (2) confined nano-size structures. For the glass formation, for example, the melt of AgI and some

Table 4 Typical sodium ion conductors

Mobile ion	Composition	Conductivity (25°C) ($S\text{ cm}^{-1}$)	Note
Na^+	$\text{Na}_2\text{O} \cdot 11\text{Al}_2\text{O}_3$	2×10^{-1} (300°C)	Na β -Alumina
	$\text{Na}_3\text{Zr}_2\text{Si}_2\text{PO}_{12}$	3×10^{-1} (300°C)	NASICON
	$\text{Na}_2\text{O}-\text{R}_2\text{O}_3-\text{P}_2\text{O}_5-\text{SiO}_2$	2×10^{-2} (300°C)	Narpsio (R=rare earth)
	Na_3PS_4	2×10^{-4} (25°C)	
	$\text{Na}_2\text{B}_{10}\text{H}_{10}$	10^{-2} (110°C)	Hydride

oxides as Ag_2MoO_4 are quenched to room temperature, whose ionic conductivity is about 10^{-3} S cm^{-1} . The confined nano-size crystals are made by various techniques such as mechanical milling, sol-gel synthesis, or after annealing of glassy materials etc., whose ionic conductivity is around $10^{-4} \sim 10^{-3}\text{ S cm}^{-1}$, as shown in [Table 2](#).

Sodium Ion Conductors

A well-known sodium ion conducting solid is so called Na β -alumina, the chemical composition of which is typically expressed as $\text{Na}_2\text{O}_{11}\text{Al}_2\text{O}_3$. The crystal has a layer structure and the incorporated sodium ions can migrate along the layer as shown in [Fig. 5](#). β'' -alumina which is represented as $\text{Na}_2\text{O} \cdot 4 \sim 6\text{ Al}_2\text{O}_3 \cdot x\text{MO}_n$ also have a layer structure and the sodium ion conductivity of these materials is higher than that of Na β -alumina. Other cations such as Ag^+ , K^+ , Li^+ , Sr^{2+} , Ba^{2+} and Eu^{2+} can be fully substituted for sodium ions in Na β -alumina and the resultant ceramics show electrical conduction due to the migration of those ions. Na β'' -alumina is used as a solid electrolyte for sodium-sulfur batteries (NaS batteries) for large-scale energy storage systems (see Section on Application Examples). Another typical sodium ion conductor is a series of NASICON, the chemical composition of which is represented as $\text{Na}_{1+x}\text{Zr}_x\text{Si}_{3-x}\text{O}_{12}$ ($x < 2$). In this type of oxide, sodium ions are surrounded by a 3D network of SiO_4 tetrahedra and ZrO_6 or PO_6 octahedra which share corners, and the sodium ions are mobile through the channel of the network structure. Glass ceramics called Narpsio of $\text{Na}_2\text{O}-\text{R}_2\text{O}_3-\text{P}_2\text{O}_5-\text{SiO}_2$ (R=rare earth), which consist of a skeleton structure of $12(\text{SiO}_4)^{4-}$ tetrahedra-membered rings exhibit high Na^+ conductivity up to 10^{-1} S cm^{-1} at 300°C and has good biocompatibility. Hollandite type 1D conductor $\text{Na}_x\text{Ti}_{2-x}\text{Ga}_{4+x}\text{O}_{11}$ has very high Na^+ conductivity only at high frequency (see Section on Fundamental Migration Mechanisms of Ions in Solid). Most of work have been done on oxide materials, however some new types of sodium ion conductors are developed; for example, as a sulfide of a cubic Na_3PS_4 is found to show $2 \times 10^{-4}\text{ S cm}^{-1}$ at 25°C and is used for an all solid state sodium battery ([Hayashi et al., 2012](#)). A very new group of ionic conductors based on boron hydrides as $\text{Na}_2\text{B}_{10}\text{H}_{10}$ is discovered to show 10^{-2} S cm^{-1} at 110°C, which has a unique icosahedral dodecahydro-closo-dodecaborate ($\text{B}_{12}\text{H}_{11}^{2-}$) anions ([Udovic et al., 2014](#); [Table 4](#)).

Lithium Ion Conductors

Recent advancement of lithium ion batteries strongly demands lithium ion conductors both for active materials for electrodes and electrolytes. As for the solid electrolytes, lithium ion conductivity of 10^{-3} S cm^{-1} is now achieved by sulfide based materials; for example, $\text{Li}_{10}\text{GeP}_2\text{S}_{12}$ shows $1.2 \times 10^{-3}\text{ S cm}^{-1}$ at 25°C ([Fig. 8](#); [Kamaya et al., 2011](#)), and some glassy or partially crystalline glasses have the same order ([Fig. 8](#)). Lithium nitride Li_3N has also 10^{-3} S cm^{-1} at room temperature. Unfortunately, however these materials are unstable under open air.

Since oxide materials are known rather stable under open atmosphere, many efforts have been devoted to find new materials with high lithium ion conductivity. The conductivity of $\text{Li}_{14}\text{Zn}(\text{GeO}_4)_4$ (named LISICON) is about $1 \times 10^{-2}\text{ S cm}^{-1}$ at 200°C and that of $\alpha\text{-Li}_2\text{SO}_4$ is extremely high ($\sim 1\text{ S cm}^{-1}$) above 573°C. Li β -alumina prepared by ion-exchange from Na β alumina shows 10^{-3} S cm^{-1} at 25°C. $\text{La}_{0.51}\text{Li}_{0.34}\text{TiO}_{2.94}$, which is a perovskite-type oxide based on $\text{La}_{2/3}\text{TiO}_3$ has high conductivity at room temperature. Glass ceramics composed of $\text{Li}_{1.55}\text{Ti}_{1.75}\text{Al}_{0.25}\text{Si}_{0.3}\text{P}_{2.7}\text{O}_{12}$ with a NASICON-type crystalline phase has $1.2 \times 10^{-3}\text{ S cm}^{-1}$ at 25°C, which is called “OHARA glass” and is commercially available. Although those oxides are stable in open air, they are reduced by a contact with lithium metal, which hampers the application to lithium battery. Some Garnet-type structured compounds as $\text{Li}_5\text{La}_3\text{Nb}_2\text{O}_{12}$, $\text{Li}_6\text{BaLa}_2\text{Ta}_2\text{O}_{12}$ and $\text{Li}_7\text{La}_3\text{Zr}_2\text{O}_{12}$ (LLZ) are found stable to the contact to lithium metal and has a reasonable conductivity of 10^{-4} S cm^{-1} at room temperature, which can be used for all-solid state lithium batteries ([Venkataraman Thangadurai et al., 2004](#)). For the application to thin film batteries, rather low conductivity glasses such as Li_3PO_4 ($\sim 10^{-6}\text{ S cm}^{-1}$ at 25°C) or its oxynitride called LIPON can be used for the electrolyte; they are stable to both lithium metal anode as well as high voltage cathodes.

An interesting new class of lithium ion conductors have been developed in hydride series starting from LiBH_4 . LiBH_4 has a lithium ion conductivity of 10^{-2} S cm^{-1} above 117°C, and its derivative of $\text{Li}_4(\text{BH}_4)(\text{NH}_2)_3$ shows $2 \times 10^{-4}\text{ S cm}^{-1}$ at room temperature ([Motoaki Matsuo et al., 2009](#)). These hydrides are stable to lithium metal, although they react with oxide cathodes.

In relation to the lithium ion battery, a great advance has been achieved in organic or organic-inorganic hybrid ion conductors, where polymer, gel, ionic liquid and plastic solids are included. In particular, organic polymers or gel electrolytes are used as the electrolyte for lithium ion batteries. The details of the organic-inorganic hybrid ion conductors are out of this colloumn; some of them are listed in [Tables 2](#) and [5](#) ([MacFarlane and Forsyth, 2001](#); [Junichi Kawamura et al., 2006, 2007](#)). The highest conductivity of
